Introduction: Cerebral small vessel disease (cSVD) is associated with microvascular and parenchymal alterations. Intravoxel incoherent motion (IVIM) MRI has been proposed to simultaneously measure both the microvascular perfusion and parenchymal diffusivity. This study aimed to evaluate the application of IVIM in cSVD to assess the microvasculature and parenchymal microstructure.

Methods: Seventy-three patients with cSVD (age 70 ± 11 y) and thirty-nine controls (age 69 ± 12 y) underwent IVIM imaging (3T). Group differences of the perfusion volume fraction f and the parenchymal diffusivity D were investigated using multivariable linear regression accounted for age, sex and cardiovascular factors. To examine the relation between the IVIM measures and the disease severity on structural MRI, white matter hyperintensity (WMH) load served as surrogate measure of the disease severity.

Results: Patients had a larger f (p < 0.024) in the normal appearing white matter (NAWM) than controls. Higher D (p < 0.031) was also observed for patients compared with controls in the NAWM and grey matter. Both f (p < 0.024) and D (p < 0.001) in the NAWM and grey matter increased with WMH load.

Conclusions: The increased diffusivity reflects the predicted microstructural tissue impairment in cSVD. Unexpectedly, an increased perfusion volume fraction was observed in patients. Future studies are needed to reveal the precise nature of the increased perfusion volume fraction. IVIM imaging showed that the increases of f and D in cSVD were both related to disease severity, which suggests the potential of IVIM imaging to provide a surrogate marker for the progression of cSVD.

1. Introduction

Age and vascular risk factor related cerebral small vessel disease (cSVD) is a common microvascular pathology underlying burdensome diseases like lacunar stroke and vascular cognitive impairment (Pantoni, 2010; Makin et al., 2013; Pantoni & Gorelick, 2011). Alterations in the parenchyma have been described in cSVD as structural MRI abnormalities like lacunes, white matter hyperintensities, microbleeds and enlarged perivascular spaces (PVS) (Wardlaw & Smith, 2013). However, little is known about the precursors of these alterations, although MRI has provided some insight in this. Using perfusion MRI, hypoperfusion was found for the white matter in patients with cSVD (Markus et al., 2000; O’Sullivan et al., 2002). Diffusion weighted imaging studies have provided indications that the loss of microstructural integrity in the white matter may be associated with cSVD (Jones et al., 1999; Chabriat et al., 1999; O’Sullivan et al., 2001). Parallel data of the microvasculature and the parenchyma in the same patient group are lacking. More pathophysiological insights may be obtained by evaluating both structures concurrently and by linking them together.

Intravoxel incoherent motion (IVIM) imaging is a non-invasive MRI technique that proposes to simultaneously measure such microvascular and parenchymal microstructural tissue properties (Le Bihan et al., 1988). In contrast to conventional diffusion weighted techniques, where the microvascular signal confounds the parenchymal signal, it is assumed that IVIM can separate the MRI effects of the...
Mental State Examination

cognitive testing or with severe cognitive impairment de-
than vascular cognitive impairment was suspected (e.g. Alzheimer’s dis-
Furthermore, participants in whom a neurodegenerative disease other
logical assessment, and extensive MRI abnormalities associated with
failure in one or more cognitive domains determined by neuropsy-
1.1) (Bamford et al., 1987). Exclusion criteria for these patients include a
syndrome with a compatible recent small subcortical infarct on brain
match on age and sex.

2. Methods

2.1. Standard protocol approvals, registrations and patient consents

This is a retrospective study and has been approved by the Medical
Ethics Committee of Maastricht University Medical Centre. All partici-
pants were included after written informed consent was obtained.

2.2. Study population

Between April 2013 and December 2014, 83 patients with clinically
manifest cSVD and 40 healthy controls were included. Participants were
included from the Maastricht University Medical Centre and Zuyderland
Medical Centre, The Netherlands. Clinically manifest cSVD was de-
defined as the occurrence of a recent lacunar stroke or the diagnosis of mild vas-
cular cognitive impairment (mVCI) due to cSVD.

 Patients with lacunar stroke (n = 44) had a first-ever acute lacunar
syndrome with a compatible recent small subcortical infarct on brain
MRI (Wardlaw et al., 2013a). If no such lesion was visible on imaging, estab-
lished clinical criteria for lacunar syndrome were used (Appendix
1.1) (Bamford et al., 1987). Exclusion criteria for these patients include a
potential cardiac embolic source (e.g. atrial fibrillation), or stenosis of
≥50% of one or both internal carotid arteries. Patients were included
3 months after the acute stroke to avoid acute stroke phase changes.

 Patients with mVCI (n = 39) had subjective cognitive complaints,
failure in one or more cognitive domains determined by neuropsy-
chological assessment, and extensive MRI abnormalities associated with
cSVD, i.e. white matter hyperintensities (WMHs) Fazekas score 3 or
Fazekas score 2 or 3, and/or with microbleeds, and/or lacunes and no
other apparent cause for the cognitive deficits (Gorelick et al., 2011).

Furthermore, participants in whom a neurodegenerative disease other
than vascular cognitive impairment was suspected (e.g. Alzheimer’s dis-
ease), with another neurological or psychiatric disease interfering with
cognitive testing or with severe cognitive impairment defined as Mini
Mental State Examination 20 and/or Clinical Dementia Rating 1,
were excluded.

Controls (n = 40) were stroke-free and had back pain or peripheral
neuropathies without (subjective) cognitive failures. Controls were
matched on age and sex.

All participants with a history of cerebrovascular disease, or other
diseases of the central nervous system or with MRI contraindications
were excluded. Baseline characteristics were recorded, including age,
sex, education (Verhage, 1964), and cardiovascular factors such as hy-
pertension (history of hypertension/antihypertensive medicine (in-
cluding calcium antagonists)), hypercholesterolemia (history of
hypercholesterolemia/statin), diabetes (history of diabetes/diabetes
medication), current smoking and body mass index (BMI).

2.3. MRI acquisition

Patients underwent brain imaging on a 3.0 Tesla MR scanner
(Achieva TX, Philips Healthcare, Best, the Netherlands) using a 32-
head coil suitable for parallel imaging. For anatomical
segmentation a T1-weighted sequence (TR/TE = 8.3/800/3.8 ms;
FOV 256 × 256 × 160 mm; 1.0 mm isotropic voxel) and a T2-
weighted FLAIR sequence (TR/TE = 4800/1650/299 ms; FOV
256 × 256 × 180 mm; 1.0 mm isotropic voxel) were performed
respectively.

IVIM imaging was conducted as described before (van Bussel et al.,
2015). In brief, a Stejskal-Tanner diffusion weighted (DW) spin
echo single shot echo planar imaging pulse sequence (TR/TE =
6800/84 ms; FOV 221 × 269 × 139 mm; 2.4 mm isotropic voxel; acq-
sition time 5:13 min) was used. To minimize the signal contamination
of CSF, an inversion recovery pulse (TI = 2230 ms) was given prior to
the DW sequence (Hales & Clark, 2012). Fifteen DW images were ac-
quired in the anterior-posterior direction using multiple diffusion sensi-
tive b-values (0, 5, 7, 10, 15, 20, 30, 40, 50, 60, 100, 200, 400, 700, and
1000 s/mm²). To increase the signal-to-noise ratio (SNR) (Appendix
1.2) at high b-values the number of signal averages for the highest
the two b-values were two and three, instead of one, respectively.

2.4. Image analysis

2.4.1. Brain segmentation

The regions of interest (ROIs) were: the normal appearing white
matter (NAWM), WMHs, deep grey matter (DGM) and the cortex. All
ROIs were automatically segmented on T1-weighted images (Freesurfer
software (Fischl et al., 2002) and FSL (v5.0) (Jenkinson et al., 2002)).

The WMHs were automatically segmented (de Boer et al., 2009) on FLAIR
images and visually checked under supervision of vascular neurologists,
who also identified and excluded infarcts and scored PVS (Appendix
1.3). The WMH load was calculated by normalizing the WMH volume to
the intracranial volume.

2.4.2. IVIM analysis

Preprocessing of the IVIM images has been described previously
(van Bussel et al., 2015) and consisted of distortion corrections (EPI
and eddy current distortions) and head displacements (ExploreDTI
v.4.8.3) (Leemans et al., 2009). Hereafter, the images were registered
to the corresponding T1-weighted image and spatially smoothed with
a 3 mm full-width-at-half-maximum Gaussian kernel. The SNR at b =
1000 s/mm² was 45 (Association NEM, 2008) (Appendix 1.2), which is
larger than the minimum value (i.e. 30) recommended for accurate
IVIM estimation (Wu et al., 2015).

The diffusion-attenuation curve is approximated with a two-com-
partment diffusion model (Le Bihan et al., 1988):

\[
S(b) = \frac{S_0}{S_0} = (1 - f) e^{-bD} + f e^{-bD^*}
\]

where \(S_0\) is the signal intensity at b-value 0 s/mm², \(S(b)\) the signal
intensity at b-value \(b\), \(f\) the perfusion volume fraction, \(D\) the parenchymal
diffusivity and \(D^*\) the pseudodiffusion coefficient. The IVIM model
considers the presence of a vascular and non-vascular compartment. The
vascular part embodies the fast water motion in blood flowing into a
network of small vessels, which has an architecture with many
microvesSEL orientations. This gives rise to the pseudodiffusion effec-
tive, hereafter called intravascular diffusivity \(D^*\), and the perfusion vol-
ume fraction \(f\). The perfusion related measure \(fD^*\) was obtained by
taking the product of \(fD^*\). The non-vascular compartment is described
by the water diffusion in the parenchymal microstructure represented
by the slower parenchymal diffusivity \(D\). To account for the CSF suppres-
sion and differences in relaxation time of blood and tissue, a modified
IVIM model (Hales & Clark, 2012) was employed (Appendix 1.4).

Model fitting was performed on a voxel-by-voxel basis using a two-
step method (Federau et al., 2014) (Appendix 1.5). This yields the IVIM
measures \(f, D^*, fD^*\) and \(D\), which were averaged over each ROI. The
analysis accounted for the goodness of fit of the model (Appendix 1.5).

2.5. Statistical analysis

To examine differences between cSVD patients and controls, inde-
pendent Student’s t-test and \(\chi^2\) test were used where appropriate. The
differences in IVIM measures between cSVD patients and controls
were analysed with an independent Student’s t-test and multivariable linear regression analysis corrected for age, sex and cardiovascular factors. In addition, differences were tested between patients with lacunar stroke and mVCI. To account for multiple comparisons a false discovery rate of 10% was applied (Benjamini & Hochberg, 1995).

To investigate the relation between IVIM measures and disease severity on MRI, the WMH load was used as the dependent variable in linear regression. Both unvariable and multivariable analyses with age, sex and cardiovascular factors were performed. This was conducted in participants, only for the IVIM measures that differed between patients and controls. Significance was inferred for p < 0.05. All statistical analyses were performed using SPSS (version 22, IBM Corp., USA).

3. Results

For this study 73 patients with cSVD (40 patients with lacunar stroke and 33 patients with mVCI), and 39 controls were suitable for analysis. Participants showing image artifacts and image processing complications (n = 11) were excluded (Appendix 1.6). Table 1 lists the characteristics of the participants. Patients and controls were well matched on age and sex. Patients were more often smokers, suffered more from hypercholesterolemia and had a lower BMI than controls. They also had a higher WMH load and more enlarged PVS in the basal ganglia. In Appendix Table 1 characteristics of patients with lacunar stroke and mVCI are shown. Patients with mVCI were older, suffered more from hypercholesterolemia and had a higher WMH load than those with lacunar stroke.

IVIM maps of a patient with cSVD and a control can be appreciated in Fig. 1. Table 2 shows the results of the perfusion volume fraction f and parenchymal diffusivity D in various ROIs. Patients have significantly higher perfusion volume fraction f than controls in all ROIs except in the WMHs. This difference remained significant after adjusting for age, sex and cardiovascular factors in the NAWM and DGM. Results of additional correction for medication and the extent of PVS can be found in Appendices 1.3 and 1.7, respectively.

Higher parenchymal diffusivity D was found in all ROIs for patients compared with controls. Parenchymal diffusivity D remained higher for patients after adjusting for age, sex and cardiovascular factors.

The results for the intravascular diffusivity D* and perfusion-related measure f·D* are provided in Appendix Table 2. No significant differences between the two groups were found for the intravascular diffusivity D* or the perfusion-related measure f·D*.

Comparison between patients with lacunar stroke and mVCI are shown in Appendix Tables 3 and 4. Patient with mVCI had higher perfusion volume fraction f (p = 0.01), intravascular diffusivity D* (p = 0.02) and perfusion-related measure f·D* (p ≤ 0.01) than patients with lacunar stroke in the DGM using univariable linear regression. Furthermore, higher parenchymal diffusivity D was observed in the NAWM for patients with mVCI than with lacunar stroke. However, when adjusting for cardiovascular risk factors and multiple comparisons, none of these differences remained significant.

Table 3 and Fig. 2 show the relation of the perfusion volume fraction f and the parenchymal diffusivity D with the WMH load in patients. Higher D in all ROIs was significantly associated with higher WMH load. Accounting for confounding effects of age, sex, and cardiovascular factors, the association weakened but remained significant. For the perfusion volume fraction f, a positive association with the WMH load was also present in all ROIs except in the WMHs. Moreover, this association remained significant (though slightly weaker) after adjusting for age, sex and cardiovascular factors.

4. Discussion

In this study, IVIM imaging was applied in cSVD for the first time. We showed that patients with cSVD exhibit a larger perfusion volume fraction f and a higher parenchymal diffusivity D in the normal appearing brain tissue (i.e. NAWM, DGM and cortex) than controls. These IVIM measures were also associated with the severity of WMH on MRI.

A higher parenchymal diffusivity for patients is in good accordance with previous studies (Chabriat et al., 1999; O’Sullivan et al., 2001; Molko et al., 2001). This measure is comparable with the better-known mean diffusivity, though without contaminating effects of the microvasculature. Higher mean diffusivity was proposed to indicate microstructural changes in tissue involving the loss of structural barriers and the increase of extracellular space (Jones et al., 1999; Chabriat et al., 1999). In our study, higher parenchymal diffusivity, and its association with the disease severity, suggest that changes in the parenchymal microstructure, which are not yet visible on conventional T2-weighted images (Fig. 1), are present in areas that may be vulnerable for potential future damage. Previously, a correlation between increased mean diffusivity and clinical disease severity was found in patients with cerebral autosomal-dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL) (Chabriat et al., 1999) using DTI.

On the contrary, our observations in the microvasculature differ with results of previous studies using other MR techniques. Reduced perfusion has been reported for patients with cSVD (Chabriat et al., 1999; O’Sullivan et al., 2001), while we found a larger perfusion volume fraction f. The interpretation of the perfusion volume fraction f is not trivial. However, the vascular nature of f has been demonstrated previously. Several studies have shown a good correlation between the perfusion volume fraction f and the cerebral blood volume using the more standard dynamic susceptibility contrast imaging (Wu et al., 2015; Federau et al., 2014; Wirestam et al., 2001). In addition, a phantom study reported that f correlated well with flow (Lee et al., 2016).

By definition, the perfusion volume fraction f is proportional to the ratio between the signal contribution from the slow diffusing water in the parenchyma and the fast diffusion arising from flowing water in the microvasculature mimicking a random walk. Several factors that might contribute to the fast diffusing component, which can lead to an increased perfusion volume fraction f, are discussed.

Firstly, the seemingly most straightforward explanation is that more water molecules flow through the microvascular network that contributes to the fast component. This can be interpreted as a network with more dilated vessels. Vasodilation might be present for patients either as a physical compensatory mechanism or as an action of antihypertensive calcium antagonists, the latter are known to act on the vascular smooth muscle cells causing vasodilation (Russell, 1988). A trend of larger perfusion volume fraction f was indeed observed for those using

Abbreviations: WMH = white matter hyperintensity; PVS = perivascular spaces. Bold values indicate significance at p < 0.05.

* Education level: low: finished high school or lower; moderate: finished intermediate vocational education; high: finished university degree (Verhage, 1964).
| These values represent participants with ≥25 PVS (Appendix 1.3).
| t-Test or chi-square.
calcium antagonists (Appendix 1.7). After adjusting for these drugs, patients with cSVD still had a larger perfusion volume fraction \( f \) than controls, which indicates that vasodilation due to medication might only explain the larger \( f \) in some degree.

Secondly, water flowing in another compartment, parallel to the microvasculature that follows the blood flow in the random network can also contribute to the fast diffusing component. Enlarged PVS corresponds with this thought, which in cSVD is caused by leakage of plasma into the perivascular space through an impaired blood-brain barrier (Wardlaw et al., 2013b; Potter et al., 2013). Indeed, a larger perfusion volume fraction \( f \) is associated with higher PVS score (Appendix 1.3).

To further investigate its contribution, linear regression was adjusted for enlarged PVS. Patients still had a larger perfusion volume fraction \( f \), but enlarged PVS remained a significant confounder indicating that it partly explains the larger \( f \).

Thirdly, water molecules that change more directions can increase the signal attenuation that contributes to the fast component. This can be depicted as increased vessel tortuosity. Previously, increased tortuosity has been shown in cSVD using histology (e.g., the retina and cerebral arteries) (Wardlaw & Pantoni, 2014; Brown & Thore, 2011; Hilal et al., 2014; Ong et al., 2013).

Briefly, previous studies have demonstrated the microvascular nature of the perfusion volume fraction \( f \). Although the interpretation of the perfusion volume fraction \( f \) is complex, we have proposed three possible factors for an increased \( f \). Future studies are needed to investigate this in more details. Furthermore, based on the observed correlation of a larger \( f \) with the severity of WMH in our study, it can be hypothesized that regions with a larger \( f \) might be indicative of areas at risk for (later) damage, which are not yet visible on conventional T2-weighted images (Fig. 1).

### Table 2

|                     | cSVD (n = 73) | Controls (n = 39) | Model 1* \( \Delta \text{Mean}(95\% \text{ CI})^d \) | \( p \)-Value | Model 2\( \beta \) | \( p \)-Value | \( R^2 \) |

\( ^* \) Unadjusted Student’s \( t \)-test.

\( ^a \) Linear regression adjusted for age, sex, and cardiovascular factors.

\( ^b \) Remained significant after testing for multiple comparisons.

\( ^d \) \( \Delta \text{Mean} \) refers to the differences in mean of the IVIM parameter between the cSVD and control group.

\( ^e \) \( \beta \) is the regression coefficient of the independent variable group (0 = control; 1 = cSVD) in the multivariable regression model.
The strength of the current study is that it was performed in a well-defined cSVD group, which indicates that findings can be clearly related to cSVD, and effects of confounders have been controlled for. Moreover, in contrast with mean diffusivity, the IVIM-derived parenchymal diffusivity \( D \) is without contaminating effects of the microvasculature and therefore provides a more accurate measure for the parenchymal integrity. Furthermore, IVIM provides the opportunity to assess the perfusion and diffusion without the use of a contrast agent, which is relevant for patients with impaired kidney function (Makin et al., 2015; Ikram et al., 2008). In addition, an inversion recovery pre-pulse was applied to minimize contamination from CSF to ensure accurate calculation of the IVIM measures.

However, this study also has a few limitations. Firstly, the IVIM technique assumes a two-compartment model, which might be an oversimplification of the actual underlying structure and also for pathological regions (i.e. WMHs) (Appendix 1.5). Secondly, we performed IVIM imaging in one direction. Imaging in more directions can provide more information on the directionality of the white matter. However, the longer scan times needed for more directions also substantially decrease patient comfort and may cause more motion artifacts. Thirdly, carotid imaging was performed to ensure changes in the small vessels were not due to large vessel pathology. We cannot fully exclude that patients with mvC1 and controls had no carotid stenosis, since no carotid imaging was performed for these participants. In addition, we do not know the precise effect of carotid stenosis on the IVIM parameters. Future studies are needed to examine their relation. Lastly, patients with mvC1 may have coexisting pathologies in addition to cSVD, for example neurodegeneration (e.g. Alzheimer’s disease). To prevent contamination as much as possible, we tried to select only the patients that were diagnosed with mvC1 most probably due to cSVD. This diagnosis was given after extensive evaluation of patient history, physical examination, neuropsychological assessment and MRI scans. Furthermore, patients showing evident atrophy in the hippocampi on MR images, which are one of the hallmarks of Alzheimer’s disease, were excluded.

To conclude, we demonstrated the first application of IVIM in cSVD. The increased parenchymal diffusivity \( D \) reflects the expected microstructural impairment in cSVD. However, the increased perfusion volume fraction \( f \) is not fully in agreement with the reported hypoperfusion in cSVD. Cautious interpretation of the perfusion volume fraction \( f \) in cSVD is needed, as \( f \) might not be purely blood flow-related. Future studies are needed to investigate this. Nevertheless, IVIM imaging showed abnormalities in both the parenchymal diffusivity \( D \) and perfusion volume fraction \( f \), which increased with disease severity. This

### Table 3

Association of perfusion volume fraction \( f \) and parenchymal diffusivity \( D \) with the WMH load in patients with cSVD.

| Model 1<sup>a</sup> | p-Value | \( R^2 \) | Model 2<sup>b</sup> | p-Value | \( R^2 \) |
|---------------------|---------|-----------|---------------------|---------|-----------|
| **Perfusion volume fraction \( f \)** |          |           |                     |         |
| NAWM                | -0.01   | 0.095     | 1.49 (0.21, 2.78)   | 0.024   | 0.389     |
| DGM                 | -0.001  | 0.207     | 1.14 (0.23, 2.05)   | 0.015   | 0.397     |
| Cortex              | -0.01   | 0.121     | 1.19 (0.25, 2.13)   | 0.014   | 0.398     |
| WMHs                | 0.13    | 0.794     | 0.132               | 0.972   | 0.328     |
|                      |         | 0.91      |                     |         |           |

| Parenchymal diffusivity \( D \) |          |           |                     |         |
| NAWM                | -0.001   | 0.436     | 253 (151, 353)      | -0.001  | 0.529     |
| DGM                 | -0.001   | 0.384     | 178 (103, 252)      | -0.001  | 0.513     |
| Cortex              | -0.001   | 0.342     | 302 (162, 443)      | -0.001  | 0.488     |
| WMHs                | -0.001   | 0.455     | 97 (66, 128)        | -0.001  | 0.588     |

NAWM = normal appearing white matter; DGM = deep grey matter; WMHs = white matter hyperintensities; CI = confidence interval; \( R^2 = \) R-squared of the linear regression model.

Bold values indicate significance at \( p < 0.05 \).

<sup>a</sup> Unadjusted Student’s t-test.

<sup>b</sup> Linear regression adjusted for age, sex, and cardiovascular factors.

\( f \) is the regression coefficient of the IVIM parameter (\( f \) or \( D \)) in the multivariable regression model where WMH load is the dependent variable.

**Fig. 2.** Association between the WMH load and the IVIM parameters \( f \) and \( D \). Scatterplots showing the unadjusted correlation between the WMH load and perfusion volume fraction \( f \) (A and B), and parenchymal diffusivity \( D \) (C and D) in the white matter (NAWM: white triangles; WMH: grey circles) and in the grey matter (DGM: grey diamonds; cortex: black crosses). The WMH load increases significantly with higher perfusion volume fraction \( f \) in the NAWM (A), DGM and cortex (B). The same effect was observed for parenchymal diffusivity \( D \) in the NAWM and WMH (C), and DGM and cortex (D).
indicates the potential of IVIM imaging to provide a surrogate marker for the progression of cSVD.
