PROBE: Predictive Robust Estimation for Visual-Inertial Navigation

Valentin Peretroukhin, Lee Clement, Matthew Giamou, and Jonathan Kelly

Abstract—Navigation in unknown, chaotic environments continues to present a significant challenge for the robotics community. Lighting changes, self-similar textures, motion blur, and moving objects are all considerable stumbling blocks for state-of-the-art vision-based navigation algorithms. In this paper we present a novel technique for improving localization accuracy within a visual-inertial navigation system (VINS). We make use of training data to learn a model for the quality of visual features with respect to localization error in a given environment. This model maps each visual observation from a predefined prediction space of visual-inertial predictors onto a scalar weight, which is then used to scale the observation covariance matrix. In this way, our model can adjust the influence of each observation according to its quality. We discuss our choice of predictors and report substantial reductions in localization error on 4 km of data from the KITTI dataset, as well as on experimental datasets consisting of 700 m of indoor and outdoor driving on a small ground rover equipped with a Skybotix VI-Sensor.

I. INTRODUCTION

Robot navigation relies on an accurate quantification of sensor noise or uncertainty in order to produce reliable state estimates. In practice, this uncertainty is often fixed for a given sensor and experiment, whether by automatic calibration or by manual tuning. Although a fixed measure of uncertainty may be reasonable in certain static environments, dynamic scenes frequently exhibit many effects that corrupt a portion of the available observations. For visual sensors, these effects include, for example, self-similar textures, variations in lighting, moving objects, and motion blur. We assert that there may be useful information available in these observations that would normally be rejected by a fixed-threshold outlier rejection scheme. Ideally, we would like to retain some of these observations in our estimator, while still placing more trust in observations that do not suffer from such effects.

In this paper we present PROBE, a Predictive ROBust Estimation technique that improves localization accuracy in the presence of such effects by building a model of the uncertainty in the affected visual observations. We learn the model in an offline training procedure and then use it online to predict the uncertainty of incoming observations as a function of their location in a predefined prediction space. Our model can be learned in completely unknown environments with frequent or infrequent ground truth data.

The primary contributions of this research are a flexible framework for learning the quality of visual features with respect to navigation estimates, and a straightforward way to incorporate this information into a navigation pipeline. On its own, PROBE can produce more accurate estimates than a binary outlier rejection scheme like Random Sample Consensus (RANSAC) [1] because it can simultaneously reduce the influence of outliers while intelligently weighting inliers. PROBE reduces the need to develop finely-tuned uncertainty models for complex sensors such as cameras, and better accounts for the effects observed in complex, dynamic scenes than typical fixed-uncertainty models. While we present PROBE in the context of visual feature-based navigation, we stress that it is not limited to visual measurements and could also be applied to other sensor modalities.

II. RELATED WORK

Two important tasks must be performed to obtain accurate estimates from navigation systems: sensor noise characterization and outlier rejection. Standard calibration techniques can provide some insight into sensor noise, but in practice, noise parameters are often manually tuned to optimize estimator performance for a given environment. Outlier rejection typically relies on front-end procedures such as Random Sample Consensus (RANSAC) [1], [2], which attempts to remove outliers before the estimator can process them, or back-end procedures such as M-estimation, which uses robust cost functions to limit the influence of large errors [3].

For visual systems, a large body of literature has also focused on compensating for specific effects such as moving objects [4], lighting variations [5], and motion blur [6] using carefully crafted models.

More general approaches for attempting to select an optimal set of features has also been investigated in the literature. In [7], visual features are parametrized in an attribute space that is used both to establish feature correspondences and
to learn a model of feature reliability for pose estimation. Sufficiently reliable features are stored for use as landmarks during pose estimation, while unreliable features are discarded. Likewise, our method maps each feature in a prediction space to a corresponding scalar weight, but we use this weight in our estimator rather than as a criterion to discard data. In more recent work [8], the authors forgo the concept of outliers in favour of finding the largest subset of coherent measurements. Once again, our method differs in that it reduces the influence of deleterious features without explicitly discarding them.

Our work on predicting the general quality of visual features is inspired by recent research on predictive covariance estimation [9], which estimates full measurement covariances by collecting empirical errors and storing them in a prediction space. For cameras, learning measurement covariances requires ground truth for the observed quantities, which is difficult to obtain for sparse visual landmarks. To relax this requirement, the authors of [10] describe an expectation-maximization technique that can serve as a proxy which is difficult to obtain for sparse visual landmarks. In contrast, our work on predicting the general quality of visual features is inspired by recent research on predictive covariance estimation [9], which estimates full measurement covariances by collecting empirical errors and storing them in a prediction space. For cameras, learning measurement covariances requires ground truth for the observed quantities, which is difficult to obtain for sparse visual landmarks.

To relax this requirement, the authors of [10] describe an expectation-maximization technique that can serve as a proxy which is difficult to obtain for sparse visual landmarks. In contrast, our work on predicting the general quality of visual features is inspired by recent research on predictive covariance estimation [9], which estimates full measurement covariances by collecting empirical errors and storing them in a prediction space. For cameras, learning measurement covariances requires ground truth for the observed quantities, which is difficult to obtain for sparse visual landmarks.

Finally, our work differs from that of [11] in how we use the linear accelerations reported by the IMU to determine metric scale [20]. Although seemingly minor, this simplification greatly reduces the complexity of the pipeline, obviates the need for a special starting state that is typically required to make gravity observable, and eliminates several sensitive tuning parameters.

We use the relatively stable rotational rates reported by commercial IMUs to extract accurate relative rotation estimates over short time periods. Similar to [19], we bootstrap a crude transformation estimate with the rotation estimate before carrying out a full non-linear point cloud alignment.

Finally, because we assume a stereo camera, the metric scale of our solution is directly observable from the visual measurements, whereas monocular VINS must rely on noisy linear accelerations to determine metric scale [20].

A. Observation Model

To begin, we outline our point feature observation model. We define two coordinate frames, \( F_a \) and \( F_b \), which represent the stereo camera pose at times \( t_a \) and \( t_b \) (where \( t_b > t_a \)), respectively. The coordinates \( p_b \) of a landmark observed in \( F_a \) can be transformed into its coordinates \( p_b \) in \( F_b \) as follows:

\[
p_b = C_{ba}(p_a - r_{ba}^a).
\]  

(1)

\( r_{ba}^a \) is a vector from the origin of \( F_a \) to the origin of \( F_b \) expressed in \( F_a \), and \( C_{ba} \) is the rotation matrix from \( F_a \) to \( F_b \).

Assuming rectified stereo images, point \( p \) is projected from the camera frame (with its origin in the centre of the left camera) into image coordinates \( y \) in the left and right cameras according to the camera model

\[
y = f(p) = \begin{bmatrix} u_l \\ v_l \\ u_r \\ v_r \end{bmatrix} = \frac{f}{z} \begin{bmatrix} x \\ y \\ x-b \\ y \end{bmatrix} + \begin{bmatrix} c_u \\ c_v \\ c_u \\ c_v \end{bmatrix}.
\]  

(2)

Here, \((x, y, z)\) are the components of \( p \), \((u_l, v_l, u_r, v_r)\) are the horizontal and vertical pixel coordinates in each camera respectively, \(b\) is the baseline of the stereo pair, \((c_u, c_v)\) is the principal point, and \(f\) is the focal length.

B. Direct Motion Solution

Assuming all landmarks are tracked correctly, our goal is to calculate the transformation from \( F_a \) to \( F_b \), parametrized by \( C_{ba} \) and \( r_{ba}^a \). We obtain an estimate for \( C_{ba} \), (denoted by \( \widehat{C}_{ba} \)) by integrating angular velocities, \( \omega_j \), from the IMU that are recorded between \( t_a \) and \( t_b \). Defining \( \psi_j : = \omega_j \Delta t \), \( \dot{\psi}_j : = |\dot{\psi}_j| \), and \( \dot{\psi}_j : = \frac{\dot{\psi}_j}{\dot{\psi}_j} \), we have

\[
\Psi_j = \cos \psi_j \mathbf{1} + (1 - \cos \psi_j) \hat{\psi}_j \hat{\psi}_j^T - \sin \psi_j \times \hat{\psi}_j,
\]  

(3)

\[
\widehat{C}_{ba} = C_{ce} \Psi_j \cdots \Psi_2 \Psi_1 C_{ce}^T.
\]  

(4)

where \( J \) is the number of IMU measurements between \( t_a \) and \( t_b \), \( C_{ce} \) is the rotation from the IMU frame to the camera frame, \( \mathbf{1} \) is the identity matrix, and \( (\cdot)^\times \) is the skew-symmetric cross-product operator. Given our rotation estimate, we can compute an estimate for translation as

\[
r_{ba}^a = -\widehat{C}_{ba}^T u_b + u_a.
\]  

(5)
where \( \mathbf{u}_a, \mathbf{u}_b \) are the point cloud centroids given by
\[
\mathbf{u}_a = \frac{1}{N} \sum_{i=1}^{N} \mathbf{p}_i^a \quad \text{and} \quad \mathbf{u}_b = \frac{1}{N} \sum_{i=1}^{N} \mathbf{p}_i^b.
\]

### C. Non-linear Motion Solution

The direct motion solution forms an initial guess \( \{ \mathbf{C}_{ba}, \mathbf{r}_{ba}^a \} \) for a non-linear optimization procedure. Given \( N \) tracked points, we wish to minimize a 3D point cloud alignment error
\[
\mathcal{L} = \frac{1}{2} \sum_{i=1}^{N} \left( \mathbf{p}_i^b - \mathbf{C}_{ba}(\mathbf{p}_i^a - \mathbf{r}_{ba}^a) \right)^T \Gamma^i \left( \mathbf{p}_i^b - \mathbf{C}_{ba}(\mathbf{p}_i^a - \mathbf{r}_{ba}^a) \right),
\]
with
\[
\Gamma^i = \left( \mathbf{G}^i_a \mathbf{R}^i_a \mathbf{G}_a^T + \mathbf{C}_{ba} \mathbf{G}^i_a \mathbf{R}^i_a \mathbf{G}^T_i \mathbf{C}_{ba} \right)^{-1},
\]
where
\[
\mathbf{G}_a^i = \frac{\partial \mathbf{g}}{\partial \mathbf{y}} \bigg|_{t(\mathbf{p}_i^b)} \quad \text{and} \quad \mathbf{G}_b^i = \frac{\partial \mathbf{g}}{\partial \mathbf{y}} \bigg|_{t(\mathbf{p}_i^b)}
\]
are the Jacobians of the inverse camera model \( \mathbf{g} := \mathbf{f}^{-1} \), and \( \mathbf{R}^i_a, \mathbf{R}^i_b \) are the covariance matrices of the \( i \)th point in image space.

We proceed by perturbing the initial guess by a vector \( \mathbf{\xi} = [\mathbf{e}^T \quad \phi^T]^T \), where \( \mathbf{e} \) is a translational perturbation and \( \phi \) is a rotational perturbation:
\[
\mathbf{r}_{ba}^a = \mathbf{r}_{ba}^a + \mathbf{e},
\]
\[
\mathbf{C}_{ba} = e^{-\phi^T} \mathbf{C}_{ba} \approx (1 - \phi^T) \mathbf{C}_{ba}.
\]

Inserting (10) and (11) into (7), we arrive at a cost function that is quadratic in the perturbations:
\[
\mathcal{L} \approx \frac{1}{2} \sum_{j=1}^{N} \left( \mathbf{\epsilon}^j + \mathbf{\tilde{\epsilon}}^j \mathbf{\xi} \right)^T \Gamma^j \left( \mathbf{\epsilon}^j + \mathbf{\tilde{\epsilon}}^j \mathbf{\xi} \right),
\]
where
\[
\mathbf{\epsilon}^j = \mathbf{p}_i^b - \mathbf{C}_{ba}(\mathbf{p}_i^a - \mathbf{r}_{ba}^a),
\]
\[
\mathbf{\tilde{\epsilon}}^j = \left[ \mathbf{C}_{ba} - (\mathbf{C}_{ba} - (\mathbf{C}_{ba}(\mathbf{p}_i^a - \mathbf{r}_{ba}^a)))^\times \right] \mathbf{p}_i^a.
\]

IV. PROBE: PREDICTIVE ROBUST ESTIMATION

The aim of PROBE is to learn a model for the quality of visual features, with the goal of reducing the impact of deleterious visual effects such as moving objects, motion blur, and shadows on navigation estimates. Feature quality is characterized by a scalar weight, \( \beta_i \), for each visual feature in an environment. To compute \( \beta_i \) we define a prediction space (similar to [9]) that consists of a set of visual-inertial predictors computed from the local image region around the feature and the inertial state of the vehicle (Section IVC details our choice of predictors). We then scale the image covariance of each feature (\( \mathbf{R}^i_a, \mathbf{R}^i_b \) in (6)) by \( \beta_i \) during the non-linear optimization.

In a similar manner to M-estimation, PROBE achieves robustness by varying the influence of certain measurements. However, in contrast to robust cost functions that weight measurements based purely on estimation error, PROBE weights measurements based on their assessed quality.

To learn the model, we require training data that consists of a traversal through a typical environment with some measure of ground truth for the path, but not for the visual features themselves. Like many machine learning techniques, we assume that the training data is representative of the test environments in which the learned model will be used.

We learn the quality of visual features indirectly through their effect on navigation estimates. We define high quality features as those that result in estimates that are close to ground truth. Our framework is flexible enough that we do not require ground truth at every image and we can learn the model based on even a single loop closure error.

#### A. Training

Training proceeds by traversing the training path, selecting a subset of visual features at each step, and using them to compute an incremental position estimate. By comparing the estimated position to the ground truth position, we compute the translational Root Mean Squared Error (RMSE), denoted by \( \alpha(l,s) \) for iteration \( l \) and step \( s \), and store it at each feature’s position in the prediction space (we denote the set of predictors and associated RMSE value by \( \Theta(l,s) \)). The full algorithm is summarized in Figure 2. Note that \( \alpha(l,s) \) can be computed at each step, at intermittent steps, or for an entire path, depending on the availability of ground truth data.

#### B. Evaluation

To use the PROBE model in a test environment, we compute the location of each observed visual feature in our prediction space, and then compute its relative weight \( \beta_i \) as a function of its \( K \) nearest neighbours in the training set. For efficiency, the \( K \) nearest neighbours are found using a \( k \)-d tree. The final scaling factor \( \beta_i \) is a function of the mean of the \( \alpha \) values corresponding to the \( K \) nearest neighbours, normalized by \( \tau_i \), the mean \( \alpha \) value of the entire training set.

The value of \( K \) can be determined through cross-validation, and in practice depends on the size of the training set and the environment. The computation of \( \beta_i \) is designed to map small differences in learned \( \alpha \) values to scalar weights
A crucial component of our technique is the choice of predictors. In practice, feature tracking quality is often degraded by a variety of effects such as motion blur, moving objects, and textureless or self-similar image regions. The challenge is in determining predictors that account for such effects without requiring excessive computation. In our implementation, we use the following predictors, but stress that the choice of predictors can be tailored to suit particular applications and environments:

1) Angular velocity and linear acceleration magnitudes
2) Local image entropy
3) Blur (quantified by the blur metric of [21])
4) Optical flow variance score
5) Image frequency composition

We discuss each of these predictors in turn.

That span several orders of magnitude. An appropriate value of randomness that can be used to characterize the texture in an image or patch. Since the quality of feature detection is strongly influenced by the strength of the texture in the vicinity of the feature point, we expect the entropy of a patch centered on the feature to be a good predictor of its quality. We evaluate the entropy $S$ in an image patch by sorting pixel intensities into $N$ bins and computing

$$S = -\sum_{i=1}^{N} c_i \log_2(c_i),$$

where $c_i$ is the number of pixels counted in the $i^{th}$ bin.

3) Blur: Blur can arise from a number of sources including motion, dirty lenses, and sensor defects. All of these have deleterious effects on feature tracking quality. To assess the effect of blur in detail, we performed a separate experiment. We recorded images of 32 interior corners of a standard checkerboard calibration target using a low frame-rate (20 FPS) Skybotix VI-Sensor stereo camera and a high frame-rate (125 FPS) Point Grey Flea3 monocular camera rigidly connected by a bar (Figure 4). Prior to the experiment, we determined the intrinsic and extrinsic calibration parameters of our rig using the Kalibr package [22]. The apparatus underwent both slow and fast translational and rotational motion, which induced different levels of motion blur as quantified by the blur metric proposed by [21].

We detected checkerboard corners in each camera at synchronized time steps, computed their 3D coordinates in the VI-Sensor frame, then reprojected these 3D coordinates into the Flea3 frame. We then computed the reprojection error as the distance between the reprojected image coordinates and the true image coordinates in the Flea3 frame. Since the Flea3 operated at a much higher frame rate than the VI-Sensor, it was less susceptible to motion blur and so we treated its observations as ground truth. We also computed a tracking error by comparing the image coordinates of checkerboard corners in the left camera of the VI-Sensor computed from both KLT tracking [23] and re-detection.

Figure 5 shows histograms and fitted normal distributions for both reprojection error and tracking error. From these distributions we can see that the errors remain approximately zero-mean, but that their variance increases with blur. This result is compelling evidence that the effect of blur on feature tracking quality can be accounted for by scaling the feature covariance matrix by a function of the blur metric.
4) Optical flow variance score: To detect moving objects, we compute a score for each feature based on the ratio of the variance in optical flow vectors in a small region around the feature to the variance in flow vectors of a larger region. Intuitively, if the flow variance in the small region differs significantly from that in the larger region, we might expect the feature in question to belong to a moving object, and we would therefore like to trust the feature less. Since we consider only the variance in optical flow vectors, we expect this predictor to be reasonably invariant to scene geometry.

We compute this optical flow variance score according to

$$\log \left( \frac{\bar{\sigma}_2^2}{\bar{\sigma}_1^2} \right),$$

where $\bar{\sigma}_2^2, \bar{\sigma}_1^2$ are the means of the variance of the vertical and horizontal optical flow vector components in the small and large regions respectively. Figure 6 shows sample results of this scoring procedure for two images in the KITTI dataset [24]. Our optical flow variance score generally picks out moving objects such as vehicles and cyclists in diverse scenes.

5) Image frequency composition: Reliable feature tracking is often difficult in textureless or self-similar environments due to low feature counts and false matches. We detect textureless and self-similar image regions by computing the Fast Fourier Transform (FFT) of each image and analyzing its frequency composition. For each feature, we compute a coefficient for the low- and high-frequency regimes of the FFT. Figure 7 shows the result of the high-frequency version of this predictor on a sample image from the KITTI dataset [24]. Our high-frequency predictor effectively distinguishes between textureless regions (e.g., shadows and roads) and texture-rich regions (e.g., foliage).

V. EXPERIMENTAL RESULTS

A. Datasets

We trained and evaluated PROBE in two sets of experiments. The first set of experiments made use of 4.5 km of data from the City, Residential, and Road categories of the KITTI dataset [24]. In the second set of experiments, we collected indoor and outdoor datasets at the University of Toronto Institute for Aerospace Studies (UTIAS) using a Skybotix VI-Sensor mounted on an Adept MobileRobots Pioneer 3-AT rover and a Clearpath Husky rover, respectively. In both cases, the camera recorded stereo images at 10 Hz while the IMU operated at 200 Hz. The outdoor dataset consisted of a 264 m training run followed by a 302 m evaluation run, with ground truth provided by RTK-corrected GPS. The indoor dataset consisted of a 32 m training run and a 33 m evaluation run through a room with varying lighting and shadows. For the indoor dataset, no ground truth was available, so we trained PROBE using only the knowledge that the training path should form a closed loop.

We compare PROBE to what we call the nominal VINS, as well as a VINS with an aggressive RANSAC routine. In the nominal pipeline, we use RANSAC with enough iterations to be 99% confident that we select only inliers when as many as 50% of the features are outliers. In the aggressive case, we increase the confidence level to 99.99%. When PROBE is used, we apply a pre-processing step that makes use of the rotational estimate from the IMU to reject any egregious feature matches by thresholding the cosine distance between pairs of matched feature vectors. We assume small translations between frames and typically set the threshold to reject feature vectors that are separated by more than five degrees.

For feature extraction, matching, and sparse optical

1 Trained using sequence 09_26_drive_0005. 2 Trained using sequence 09_26_drive_0046. 3 Trained using sequence 09_26_drive_0015. † This residential trial was evaluated with a model trained on a sequence from the city category because of several moving vehicles that were better represented in that training dataset.

![Image of KITTI dataset environments](image1)

**Fig. 8.** Three types of environments in the KITTI dataset, as well as 2 types of environments at the University of Toronto. We use one trial from each category to train and then evaluate separate trials in the same category.

![Image of Clearpath Husky rover](image2)

**Fig. 9.** Our four-wheeled skid-steered Clearpath Husky rover equipped with Skybotix VI-Sensor and Ashtech DGPS antenna used to collect the outdoor UTIAS dataset.

flow calculations, we use the open source vision library **LIBVISO2** [18]. LIBVISO2 efficiently detects thousands of feature correspondences by finding stable features using blob and corner masks and matching them by comparing Sobel filter responses. For all prediction space calculations, we use features in the left image of the stereo pair.

**B. Training**

Sample results of the training procedure described in Section IV are illustrated in Figure 10 for data from the Residential category. As ground truth is available for each image, we compute the RMSE at every frame, and only iterate over the path 10 times. Note the large variance of training run error in the sharp turn in Figure 10 caused by a car that drives through the camera’s field of view. PROBE is able to distinguish features on the car and adequately reduce their influence with the final learned model.

**C. Evaluation**

To evaluate PROBE, we run the nominal VINS (cf. Section III) on a given test trial, tune the RANSAC threshold to achieve reasonable translation error (<5% final drift), then...
Fig. 11. A 234 m KITTI test run in the City category, sequence 09_29_drive_0071 containing numerous pedestrians and dramatic lighting changes. PROBE is able to produce more accurate navigation estimates than even an aggressive RANSAC routine.

Fig. 12. A 667 m test run in the Residential category, sequence 09_30_drive_0027. PROBE is better able to deal with a static portion when a large shadow and moving vehicle cross the field of view of the camera.

Fig. 13. A 440 m test run in the Road category, sequence 09_26_drive_0027. PROBE is able to better predict a large moving vehicle, and extract higher quality features from dense foliage. Note the difference in scale between the two axes.

Fig. 14. Test and training trials in the outdoor UTIAS environment. The rover traverses a snowy landscape and people walk though the field of view.

Fig. 15. A 32.8 m test run in our indoor UTIAS dataset. The subplot in the bottom-right corner of the figure shows that PROBE reduces drift in the vertical (y) direction more than the nominal VINS and aggressive RANSAC.

VI. DISCUSSION

In most of the datasets we evaluated, PROBE performed as well as or better than a standard RANSAC routine in reducing the influence of deleterious features. Finally, we run VINS again, this time disabling RANSAC completely and applying our trained PROBE model (with pre-processing) to each observed feature. Table I compares the performance of each trained PROBE model to that of the nominal and aggressive-RANSAC VINS. In the best case, PROBE achieves a final translational error norm of less than half that of both reference VINS. Figures 11, 12, and 13 reveal problematic sections of the KITTI dataset where PROBE is able to significantly improve upon the performance of both reference VINS. Moving vehicles and pedestrians are the most obvious sources of error that PROBE is able to identify. The datasets also included more subtle effects such as motion blur (notable at the edge of images), slowly swaying vegetation, and shadows.
ows, large moving objects, and self-similar textures. Often, PROBE can produce more accurate navigation estimates by intelligently weighting measurements to reflect their quality while still exploiting the information contained in low-quality measurements. In this sense, PROBE can be thought of as a soft outlier classification scheme, while RANSAC rejects outliers based on binary classification.

Like with other machine learning approaches, a good training dataset is essential to producing an accurate and generalizable model. PROBE is flexible enough that it can be taught with varying frequency of ground truth data. For instance, in the outdoor dataset collected at UTIAS, GPS measurements were available at only 1 Hz, and PROBE was trained by evaluating the ARMSE over the entire path. For the indoor dataset, no ground truth was available and was trained by evaluating the ARMSE over the entire path. Measurements were available at only 1 Hz, and PROBE instance, in the outdoor dataset collected at UTIAS, GPS

VII. CONCLUSIONS

In this work, we presented PROBE, a novel method for predicting the quality of visual features within complex, dynamic environments. By using training data to learn a mapping from a predefined space of visual-inertial predictors to a scalar weight, we can adjust the influence of individual visual features on the final navigation estimate. PROBE can be used in place of traditional outlier rejection techniques such as RANSAC, or combined with them to more intelligently weight inlier measurements.

We explored a variety of potential predictors, and validated our technique using a visual-inertial navigation system on over 4 km of data from the KITTI dataset and 700 m of indoor and outdoor data collected at the University of Toronto Institute for Aerospace Studies. Our results show that PROBE outperforms RANSAC-based binary outlier rejection in many environments, even with only sparse ground truth available during the training step.

In future work, we plan to examine a broader set of predictors, and extend the training procedure to incorporate online learning using intermittent ground truth measurements or loop closures detected by a place recognition thread. Further, we are interested in analyzing the amount of training data required for a given improvement in navigation accuracy, and in investigating PROBE’s effect on estimator consistency.
