(Dated: December 30, 2013)

Using first-principles methods based on density-functional theory we investigate the spin relaxation in W(001) ultrathin films. Within the framework of the Elliott-Yafet theory we calculate the spin mixing of the Bloch states and we explicitly consider spin-flip scattering off self-adatoms. We find an oscillatory behavior of the spin-mixing parameter and relaxation rate as a function of the film thickness, which we trace back to surface-state properties. We also analyze the Rashba effect experienced by the surface states and discuss its influence on the spin relaxation. Finally we calculate the anisotropy of the spin-relaxation rate with respect to the polarization direction of the excited spin population relative to the crystallographic axes of the film. We find that the spin-relaxation rate can increase by as much as 47% when the spin polarization is directed out of plane, compared to the case when it is in plane. Our calculations are based on the multiple-scattering formalism of the Korringa-Kohn-Rostoker Green-function method.

I. INTRODUCTION

In the process of spin relaxation an excited electron spin population returns to the state of equilibrium that, in nonmagnetic materials, corresponds to zero spin polarization. Despite the fact that the fundamental mechanisms contributing to spin relaxation have been investigated since a long time in various systems, the phenomenon still attracts attention, owing to its importance in spintronics applications for example in giant magnetoresistance or, lately, in the spin Hall effect as well as the inverse spin Hall effect that is used to probe spin currents. We mention these examples among a variety of applications in order to stress the practical importance of spin relaxation in thin metallic films, which is part of the motivation for the present work, as a source of loss of spin-mediated information.

There are various mechanisms that can contribute to spin relaxation and in metallic systems they are mostly related to Fermi-surface properties. Although it is clear that in a nonmagnetic metal or metallic film the spin relaxation can be attributed to spin-flip scattering in the presence of the spin-orbit coupling (SOC), many parameters come into play, and one expects the spin-relaxation rate to depend strongly on the film’s crystallographic orientation, its thickness and details of the Fermi surface. Of particular importance here can also be the Rashba states created as a result of spin-orbit interaction acting on the surface bands in the film

In this work we present a study of free-standing W(001) films with space-inversion symmetry where we consider that the spin-flip scattering is induced by W adatom impurities. The motivation for restricting the investigation to free-standing films is that we consider them to be generic prototypes for films in layered structures if the material “sandwiching” the film — the surrounding matrix — is insulating. There is no question that contact at the film surfaces will produce effects that depend on the surrounding matrix, however, we are searching here for physical mechanisms that can in principle still be present in the contact case, even if the details of the band structure are different. In the present analysis we will face e.g. oscillatory effects arising from the thickness dependent interaction of surface states that can be replaced by interface states if the films are sandwiched; also, the low dimensionality entails an anisotropy of spin relaxation that should be a quite general effect irrespective of the film contact. Due to the pronounced manifestation of such effects, bcc W(001) films are chosen among 5d transition-metal thin films for a deeper analysis in the present work.

In the presence of structural inversion symmetry, which is the case here in bcc(001) films, the Elliott–Yafet mechanism plays the most important role for spin relaxation. Within this mechanism, the relaxation is realized via spin-orbit mediated spin-flip scattering off impurities at low temperatures and additionally off phonons at higher temperatures. According to Elliott, in a system with time-reversal and space-inversion symmetry there are two degenerate Bloch states at each k-point, which can be written as superpositions of up |↑⟩ and down |↓⟩ spinors:

\[
\Psi_k^+(r) = (a_k(r)|↑⟩ + b_k(r)|↓⟩) e^{i\mathbf{k} \cdot \mathbf{r}} \quad \text{and} \quad \Psi_k^-(r) = (a_k^*(r)|↓⟩ - b_k^*(r)|↑⟩) e^{i\mathbf{k} \cdot \mathbf{r}}.
\]

Due to the degeneracy there is an arbitrariness in the selection of \(a_k(r)\) and \(b_k(r)\), as any superposition of the states in Eq. \(1\) is also an eigenstate of the Hamiltonian. In practice the arbitrariness is usually lifted by the demand that the spin expectation value of \(\Psi_k^+\) should be maximal in the z direction, or actually in any chosen direction \(\hat{\mathbf{n}}\) (that we call the spin-quantization axis, SQA) experimentally defined by the polarization direction of the excited spin population. The spin polarization vector \(S_k^\pm\) corresponding to \(\Psi_k^\pm\) can be calculated via

\[
S_k^\pm = \frac{1}{2} \langle \Psi_k^\pm | \sigma | \Psi_k^\pm \rangle, \quad i = x, y, z,
\]

where \(\sigma\) is the vector of Pauli matrices (atomic units with \(\hbar = 1\) are implied). The two degenerate wavefunctions at each
It is straightforward to show the relation of the spin projection along the SQA, \( \hat{s} \cdot S_k^- \), to \( a_k(r) \) and \( b_k(r) \):

\[
\begin{align*}
a_k^2 &:= \int |a_k(r)|^2 \, d^3r = \frac{1}{2} + \hat{s} \cdot S_k^+, \\
b_k^2 &:= \int |b_k(r)|^2 \, d^3r = \frac{1}{2} - \hat{s} \cdot S_k^+,
\end{align*}
\]

(4)

where we have also introduced the integrals \( a_k^2 \) and \( b_k^2 \). Taking an average over the Fermi surface (FS) (actually Fermi lines in the present two-dimensional case), the Elliott-Yafet parameter (EYP) is obtained as

\[
b^2 = \langle b_k^2 \rangle_{FS} = \frac{1}{n(E_F)V_{BZ}} \int_{FS} dk \, \frac{b_k^2}{v_F(k)},
\]

(6)

where \( v_F(k) \) is the Fermi velocity, \( n(E_F) \) is the density of states at the Fermi level \( E_F \) and \( V_{BZ} \) is the Brillouin zone volume.

Momentum scattering events couple the spin-up and down components of the wavefunctions at different momenta, allowing for transitions between \( \Psi_k^+ \) and \( \Psi_k^- \), and giving rise to spin relaxation. In the Elliott approximation\(^4\), the spin-flip probability rate of state \( \Psi_k^+ \), \( P^{+\rightarrow+} \), is proportional to the momentum-dependent spin-mixing parameter \( b_k^2 \). As a result, after taking an average over the Fermi surface, the ratio between the spin-relaxation rate \( 1/T_1 \) and momentum-relaxation rate \( 1/T_p \), \( T_1^{-1}/T_p^{-1} \), is proportional to \( b^2 \). Departing from the Elliott approximation, in which \( b^2 \) is assumed small, one has to take into account the form of the scattering potential \( \Delta V \) of the impurity (W adatom in this case) and calculate the scattering T-matrix, \( T(E) = \Delta V (1 - G(E)\Delta V)^{-1} \), where \( G(E) \) is the Green function of the unperturbed film. Then, the spin-conserving and spin-flip probability rates are given by the squared matrix elements \( P^{++} = 2\pi |\langle \Psi_k^+ | T(E_F) | \Psi_k^+ \rangle|^2 \) and \( P^{+-} = 2\pi |\langle \Psi_k^- | T(E_F) | \Psi_k^+ \rangle|^2 \), respectively. Fermi-surface integrals of the scattering probability yield the average momentum- and spin-relaxation rate per k-point

\[
T_1^{-1}(k) = 2T_{sf}^{-1}(k) = \frac{c}{V_{BZ}} \int_{FS} dk' \, \frac{P^{++} + P^{+-}}{v_F(k')},
\]

(7)

and k-averaged

\[
T_1^{-1} = 2T_{sf}^{-1} = \frac{1}{n(E_F)V_{BZ}} \int_{FS} dk \, \frac{T_1^{-1}(k)}{v_F(k)}
\]

(9)

\[
T_p^{-1} = \frac{1}{n(E_F)V_{BZ}} \int_{FS} dk \, \frac{T_p^{-1}(k)}{v_F(k)}
\]

(10)

with \( c \) the concentration of impurities. The factor 2 in the definition of \( T_1 \) with respect to the spin-flip time \( T_{sf} \) has a historical origin as \( T_1 \) was derived from the full linewidth at half-amplitude of conduction electron spin resonance spectra.\(^3\)

In the literature, \( T_1 \) is usually mentioned as the measured quantity, but from the point of view of scattering theory it is more natural to use \( T_{sf} \).

It is clear that the spin-mixing parameter \( b^2 \) reflects the host contribution to the spin relaxation while the spin-relaxation time \( T_1 \) contains also the scattering contribution of the impurity which of course depends on the type of impurity as well as impurity concentration. In the present work, we will first discuss the spin-mixing parameter to understand general features of spin relaxation in W(001) thin films. After that, by introducing a W adatom on one film surface, we will investigate the spin-relaxation rate \( T_1^{-1} \) quantitatively. The spin-quantization axis \( \hat{s} \) is at first chosen perpendicular to the surface of the films, but later we also examine a variation of the quantization axis revealing anisotropic effects in spin relaxation. The variation of the quantization axis corresponds to an experimental situation where the spin polarization of the injected spin population (or the magnetic field direction in an electron spin resonance experiment) is changed.

We find that the EYP acquires very large values owing to the Rashba effect at the surface and also exhibits an even-odd oscillation with the thickness of the films following the behavior of the electronic structure of the surface bands; the same is true for the spin-relaxation rate due to scattering off W adatoms. These effects are the subjects of Sec. II and III. We then present in Sec. IV the anisotropy of the EYP and of the spin-relaxation rate with respect to the choice of the SQA. Finally in Sec. V we argue that, as far as the spin relaxation in the surface states is concerned, the mechanism discussed and calculated here should be dominant over, e.g., the Dyakonov-Perel mechanism, prominent in semiconductors or semiconductor heterostructures where Rashba-type of splitting is also present but has a much lower magnitude.

Our investigation is based on density-functional calculations within the local density approximation.\(^19\) We employ the full-potential Korringa-Kohn-Rostoker (KKR) Green function method\(^20\) with exact treatment of the atomic cell shapes.\(^21\) After a self-consistent full-potential calculation performed within the scalar-relativistic approximation, spin-orbit coupling is added when calculating the Fermi surface properties and the scattering-matrix elements. The formalism for the calculation is given in detail in Ref. \(9\). A similar formalism\(^22\) has been applied before in Refs. \(22,23\) where the results compared well with experiment. An angular momentum cutoff of \( l_{\text{max}} = 3 \) is taken. We use the experimental lattice constant of bcc tungsten of \( a = 3.165 \) Å. For an interpretation of our results and a separation of causes we perform in some cases numerical experiments by switching on and off the spin-orbit coupling in the system. The W adatom impurity is treated using the Jülich KKR impurity-embedding code (KKR营收) which enables us to treat with the charge and spin-density self-consistently including the perturbation of the nearest neighbors of the impurity. Lattice relaxations are not taken into account.

It should be mentioned that W(001) films have been a subject of intensive theoretical and experimental reasearch for a long time, cf. Refs. \(24,25\) and citations therein. It is known that at low temperatures the W(001) surface under-
II. EVEN-ODD EFFECT IN SPIN-MIXING PARAMETER AND SPIN-RELAXATION RATE

We first present our results on an unexpected even-odd oscillatory variation that we observed in the Elliott-Yafet parameter of the film and the spin-relaxation rate due to a W adatom with respect to the number of layers in the W(001) film.

To start the discussion, we take a look at the comparison of the density of states (DOS) of W bulk and a typical representative of the films studied in the following — a 7-layer W(001) film — shown in Fig. 1. In this particular calculation the spin-orbit coupling was not included. Characteristic of a transition metal with bcc structure, the bulk DOS shows a bimodal behavior with a dip in the middle separating bonding from antibonding states, which for W lies at the Fermi energy. This structure of the DOS is also clearly preserved in the center of the thin W(001) film. In contrast, the local DOS in the surface atomic layer of the film displays a peak at $E_F$, which can be attributed to the presence of surface states. Obviously, this should result in a significant surface contribution to the Fermi-surface-dependent quantities and in particular the Elliott–Yafet parameter. The DOS of W(001) films of different thickness, considered later, are very similar to those in the case of a 7-layer film.

Next, we include the spin-orbit coupling, choose the spin-quantization axis perpendicular to the film ($\hat{z}|[001]$) and calculate the Fermi surfaces and the distribution of the spin-mixing parameter $b^2_k$ for W(001) films of varying thickness. The results are presented in Fig. 2. The most important feature for our study are the surface states. These are indicated as “S1” and “S2,” and pointed at by arrows in the vicinity of the $\bar{M}$ point on the Fermi surface. S1 and S2 are present at all film thicknesses and we will discuss them in more detail below. Here we merely note for clarity that the S2-line merges into bulk-like states. Additionally, the bcc structure of W(001) films has been extensively studied owing to its multiple applications as a substrate used for deposition. 

Recently, because of the strong spin-orbit interaction W(001) goes a $c(2 \times 2)$ reconstruction, while the ideal structure is restored at higher temperatures. Additionally, the bcc structure of W(001) films has been extensively studied owing to its multiple applications as a substrate used for deposition. Recently, because of the strong spin-orbit interaction W(001) is used as substrate for ultrathin magnetic films generating a strong Dzyaloshinski-Moriya interaction introducing complex magnetic structures. However, most important for our study are the surface states. Together with Cu(111), W(001) is one of the first systems for which surface states were predicted to exist theoretically.

Another feature of W(001) films — shown in Fig. 1. In this particular calculation representative of the films studied in the following — a 7-layer W(001) film — shown in Fig. 1. In this particular calculation the spin-orbit coupling was not included. Characteristic of a transition metal with bcc structure, the bulk DOS shows a bimodal behavior with a dip in the middle separating bonding from antibonding states, which for W lies at the Fermi energy. This structure of the DOS is also clearly preserved in the center of the thin W(001) film. In contrast, the local DOS in the surface atomic layer of the film displays a peak at $E_F$, which can be attributed to the presence of surface states. Obviously, this should result in a significant surface contribution to the Fermi-surface-dependent quantities and in particular the Elliott–Yafet parameter. The DOS of W(001) films of different thickness, considered later, are very similar to those in the case of a 7-layer film.

Next, we include the spin-orbit coupling, choose the spin-quantization axis perpendicular to the film ($\hat{z}|[001]$) and calculate the Fermi surfaces and the distribution of the spin-mixing parameter $b^2_k$ for W(001) films of varying thickness. The results are presented in Fig. 2. The most important feature for our study are the surface states. These are indicated as “S1” and “S2,” and pointed at by arrows in the vicinity of the $\bar{M}$ point on the Fermi surface. S1 and S2 are present at all film thicknesses and we will discuss them in more detail below. Here we merely note for clarity that the S2-line merges into bulk-like states. Additionally, the bcc structure of W(001) films has been extensively studied owing to its multiple applications as a substrate used for deposition. Recently, because of the strong spin-orbit interaction W(001) goes a $c(2 \times 2)$ reconstruction, while the ideal structure is restored at higher temperatures. Additionally, the bcc structure of W(001) films has been extensively studied owing to its multiple applications as a substrate used for deposition.
decomposition was performed by integrating in Eq. 6 over
only the surface-state part or only the bulk-state part of the
Fermi surface, while keeping the denominator \( n(E_F) \) fixed at
the value of the total density of states. It is striking that for
all considered film thicknesses the overall contribution of the
surface states to the EYP is comparable, or even larger than,
the bulk contribution. It is well known that the amplitude of
the surface states drops exponentially as a function of distance
from the surface. Therefore, in the limit of large film thick-
ness up to 10 layers.

If we examine the distribution of \( b_k^2 \) on the Fermi surface
for several film thicknesses, presented in Fig. 2, it becomes
apparent that \( b_k^2 \) exhibits large variations in magnitude, both
as a function of the position at the Fermi surface as well as the
film thickness. We also clearly observe that among all states at
the Fermi surface the largest spin-mixing occurs in the surface
states S1 and S2.

Let us try to understand the oscillation with film thickness
starting from the band structure and symmetry properties of
the surface states. We consider the surface states in the ab-
sence of spin-orbit coupling because it is simpler to apply
symmetry arguments in this case. We name the states S1′ and
S2′ where the primed indices are used to distinguish the case
without SOC; S1′ and S2′ are mixed with each other under the
action of the SOC Hamiltonian to produce S1 and S2.

FIG. 3: (Color online) Top: The dashed lines show the thickness de-
pendence of the Elliott–Yafet parameter in W(001) thin films with
the SQA perpendicular to the film. The total EYP (squares) is de-
composed into contributions from the surface states S1 and S2 (tri-
angles) and from the bulk states (diamonds) of the film. The full
line (circles) shows the ratio between spin-flip rate and momentum-
relaxation rate, \( T_s^{-1}/T_p^{-1} \) for the case of self-adatom scattering [W
adatom on W(001)]. The even-odd effect is evident in the ratio fol-
lowing very closely the oscillation of the Elliott-Yafet parameter.
Bottom: Splitting of the state S2′ (without SOC) due to the inter-
action between the two surface states of opposite surfaces (see Fig.
for the band structure and for the position where the splitting of S2′
is calculated). The oscillatory behavior of the splitting as function of
film thickness correlates with the behavior of the EYP and spin-flip
rate. The lines are guides to the eye.

FIG. 4: (Color online) The band structure of 6- and 7-layer W(001)
films with (filled blue squares) and without (red open circles) spin-
orbit coupling. Arrows mark the surface states S1 and S2 correspond-
ing to the calculation with SOC and S1′ and S2′ corresponding to
the calculation without SOC. An even-odd effect in the thickness-
dependent splitting of S2′ is responsible for the even-odd effect in
the EYP.
We consider the band structure of S1’ and S2’ along the ΓM diagonal of the Brillouin zone (red open circles in Fig. 4). S1’ and S2’ comprise mainly d orbitals. We set a coordinate system with x and y along the [100] and [010] directions in the surface and z normal to the surface. We distinguish two types of d orbitals with respect to their reflection properties about the diagonal [110] (ΓM): even \[ \frac{1}{\sqrt{2}}(d_{xz} + d_{yz}), \] \[ d_{xy}, \] and odd \[ \frac{1}{\sqrt{2}}(d_{xz} - d_{yz}) \] and \[ d_{xz}, d_{yz} \]. Staying on the high-symmetry line \( k \in \Gamma M \), the Bloch states \( \Psi_k(r) \) derived from odd orbitals show nodes along the [110] diagonal, which has a consequence of a high in-plane kinetic energy, not leaving enough energy for penetration into the bulk region. Therefore, the odd-d-orbital surface states of the opposite surfaces couple very weakly to each other and show an almost vanishing splitting already at small film thicknesses. On the other hand, the even states, relieved from this nodal structure, have less in-plane kinetic energy and thus enough energy to penetrate into the bulk region and hybridize with their likes of the opposite surface; then the resulting hybrids show a splitting even at larger thicknesses. This parity-dependence of the surface states was observed in the past by Mattheiss and Hamann.\[26\]

The consequence of this can be seen e.g. in Fig. 4 for the bands without spin-orbit coupling along ΓM where the S2’ bands show a large splitting whereas the bands S1’ show an almost complete degeneracy.

The even-odd effect of the EYP of state S2 can now be traced back to surface state S2’. The aforementioned splitting of S2’ due to the interaction between the opposite surfaces exhibits an even-odd behavior: for an even number of layers the splitting is large, for odd it is considerably smaller due to an oscillatory behavior. This can be seen in Fig. 3 (bottom panel) where the splitting of S2’ has been calculated at the position indicated by arrows in Fig. 4. One immediately recognizes the striking correlation between the oscillations in the splitting of S2’ and in the EYP shown in the same figure. We should comment that the origin of the even-odd effect in the coupling could not be fully explained by the symmetry properties of the wavefunctions. However, it is clear that owing to the different inversion symmetry center in even- and odd-layer films, the overlap between the opposite-side surface states is different which contributes to the even-odd effect.

Including the SOC, the even-odd dependence of the energy splitting will have a profound effect on the spin-mixing parameter, since the energy distance between states affects crucially the value of \( b_k \) in Eq. (11). To justify this statement, we remind the reader of Elliott’s perturbative expansion for the \( n \)-th band a summation over all other bands \( n’ \neq n \) should be performed, reading \( b_{nk}^2 = \sum_{k} |(\Psi_{nk}^0|\xi|LS)^{1/2}|(\Psi_{nk}^0)^{1/2}/(E_{nk}^0 - E_{nk}^0)^2 \) in first order perturbation theory, where the superscript 0 refers to the wavefunctions and eigenstates without SOC, \( \xi \) is the SOC strength and \((LS)^{1/2}\) is the spin-flip part of SOC operator. Since the energy difference of the states appears in the denominator (in all orders of the perturbation expansion), changing the energy splitting will strongly affect the value of \( b_k^2 \). Thus emerges the correlation between the splitting of S2’ without SOC and the EYP with SOC in Fig. 5.

Now we investigate the spin relaxation due to the W adatom impurities located on one film surface. In the upper panel of Fig. 5 we also show the ratio between the spin-flip rate and momentum-relaxation rate, \( T_{sf}^{-1}/T_p^{-1} \), as a function of the film thickness. We see that the magnitude of the ratio is of the same order as the Elliott-Yafet parameter and that the oscillatory behavior of the two quantities is clearly correlated, even though Elliott’s approximate relation \( T_{sf}^{-1}/T_p^{-1} \approx 4b^2 \) does not hold. The deviation from Elliott’s approximation is not surprising since it holds under the assumptions that \( b^2 \) is small and that the scattering is weak enough to be described within first-order perturbation theory. In any case the high values of \( T_{sf}^{-1}/T_p^{-1} \), of the order of 0.3-0.4, show that approximately every third scattering event includes a spin-flip. This high spin-flip rate is certainly related with the fact that a W adatom introduces an additional contribution to spin-flip scattering via its internal spin-orbit coupling. It can be remarked that the ratio between spin-flip rate and momentum-relaxation rate does not depend on the impurity concentration, but the values of the two quantities separately do. In order to have a quantitative estimate, the impurity concentration \( c \) in Eq. (7) and (8) is set to be 1%. This gives us, for example, a value of the spin-relaxation rate of 11.63 ps\(^{-1}\)/at% and momentum-relaxation rate of 13.69 ps\(^{-1}\)/at% for a 10-layer W(001) thin film by scattering off W adatoms. We will return to the spin relaxation rate in Sec. IV.

### III. RASHBA-CHARACTER OF SURFACE STATES

This section is dedicated to the investigation of the Rashba effect at the W(001) surface. The essence of the Rashba effect at surfaces lies in a crystal-momentum dependent splitting of surface states due to the presence of spin-orbit coupling together with the structural inversion asymmetry caused by the surface.\[20\] As was first observed experimentally in Au(111) by LaShell et al.\[36,37\] and then theoretically explained by Henk and co-workers\[11\] the surface states of Au(111) display a SOC-derived dispersion relation very similar to that of the two-dimensional electron gas (2DEG) described by a two-band Rashba model.\[22\] One signature of the Rashba effect is a Fermi surface consisting of two concentric rings with the spin polarization perpendicular to the group velocity but pointing in opposite directions at each of the rings. We will refer to the resulting k-space spin texture as spin-polarization field in the following (which is closely related to the spin-orbit field defined e.g. in Ref. 5).

The Rashba splitting results in a degeneracy lifting where the pairing implied by Eq. (1) does not hold any more. Since the effect originates in the broken inversion symmetry at the surface, it can be captured computationally by treating half-infinite systems or by breaking the symmetry between two surfaces of a finite symmetric slab via deposition on a substrate or adsorption of a monolayer of a different material on one surface of the slab, e.g. a Cu monolayer on an Au film\[33\] or H adsorption on W(111)\[39\]. Here, we follow an alternative approach, keeping the inversion symmetry but projecting out the appropriate state from the doubly degenerate subspace de-
FIG. 5: (Color online) Top: Schematic diagram showing the energy levels of the Rashba states at the film surfaces and their hybridization when the film thickness is finite and the states of opposite surfaces interact. The full lines represent the energy levels before and after hybridization and the dashed lines show which level pairs are hybridized. Bottom: The spin polarization of the surface states around the M-point of an 11-layer W(001) film. The direction of the spin polarization is given by arrows, while its magnitude is given by means of a color code of the arrows. Surface states S1 and S2 are marked.

We introduce an intuitive view of our approach by means of a schematic energy level diagram in Fig. 5 (top). We first imagine the film in the limit of infinite thickness, with the states of each surface not interacting with the opposite surface. Then, a Rashba splitting occurs due to SOC. Fixing a k-point on the surface band, the splitting results in spin-polarized levels |L ↑⟩ and |L ↓⟩ on the left surface (indicated by L) and similarly |R ↑⟩ and |R ↓⟩ on the right surface. The Rashba splitting Δ is the same in the two surfaces but the order with respect to energy in which the levels of spin polarization ↑ and ↓ occur is reversed in the two surfaces because of the opposite direction of the surface normal, according to standard Rashba theory. Reducing the film thickness, the left and right states interact via a hopping t (let us assume t ≪ Δ) and hybrid states are formed with bonding (B) and antibonding (A) nature: |B ↑⟩ ≈ |L ↑⟩ + ±Δ |R ↑⟩, |A ↑⟩ ≈ −Δ |L ↑⟩ + |R ↑⟩. Thus, |B ↑⟩ is localized more on the left surface and |A ↑⟩ more on the right surface. Analogously, hybrids |B ↓⟩ and |A ↓⟩ are formed. A calculation of the film band structure finds linear combinations of the degenerate bonding α|B ↑⟩ + β|B ↓⟩ as well as antibonding α|A ↑⟩ + β|A ↓⟩ hybrids; such linear combinations are basically the degenerate wavefunctions Ψ± k describing Eq. (1) in the particular case of surface states. Returning to the notation of Eq. (1), it has then to be decided which particular linear combination is of interest for the physics of the problem at hand. For instance, for the calculation of the EYP in the previous section the linear combinations were chosen so that the spin expectation value along the z direction was maximized. Here, on the other hand, we want to choose constants αk and βk (not depending on r) in such a way that the combination αkΨk↑ + βkΨk↓ resembles as much as possible the Rashba states of the infinite-thickness film; i.e., in a way that the wavefunctions |B ↑⟩, |B ↓⟩, |A ↑⟩, and |A ↓⟩ of Fig. 5 are retrieved. For this reason we pick one surface, say the left, and we find the linear combination that maximizes the spin expectation value within the particular surface atomic layer and call the resulting wavefunction Ψmax,L k = αkΨk↑ + βkΨk↓. We thus define the polarization in the surface layer as

\[ \langle S_k^{surf} \rangle = \frac{1}{2} \int_{surf.layer} \left[ \Psi_{k,L}^\dagger(r) \sigma^i \Psi_{k,L}^\dagger(r) \right] d^3r, \tag{11} \]

where \( i \in \{x, y, z\} \), and demand that αk and βk are such that \( \langle S_k^{surf} \rangle = \sqrt{(S_k^{surf})^2 + (S_k^{surf})^2 + (S_k^{surf})^2} \) is maximized. Then we observe that Ψmax,L k has both the spin and charge density more localized on the left surface (numerical result not shown here explicitly). Since the film potential in our calculation is still inversion-symmetric, Ψmax,L k = αkΨk↑ + βkΨk↓ has an orthogonal degenerate partner, Ψmax,R k = c^* k Ψk↓ − βkΨk*, which is more localized on the opposite surface and has the opposite spin expectation value. We say “more localized” and not “completely localized” because Ψmax,L/L k is still left-right hybrids but each has higher amplitude on its representative surface. Thus, we have conveniently separated the degenerate surface states in a way that they naturally evolve into the single surface state case in the limit of infinite film thickness. It should be stressed here that maximization \( \langle S_k^{surf} \rangle \) is only the means of choosing a reasonable approximation to the single-surface state. However, we analyze the resulting spin-polarization field by calculating the spin expectation value of Ψmax,L/ k over all layers, \( \langle S_k \rangle = \frac{1}{2} \int_{surf.layer} \left[ \Psi_{k,L}^\dagger \sigma \Psi_{k,L}^\dagger \right] d^3r \).

In Fig. 5 we present our results on the spin-polarization field, represented by arrows, for an 11-layer W(001) film. The figure is focused on the area of reciprocal space around the M-point, i.e., partly outside the first Brillouin zone, to show the contours which correspond to the surface states S1 and S2. The starting point of each arrow corresponds to a k-point on the Fermi surface, the direction of the arrow to the direction of \( \langle S_k \rangle \), and the color code to its magnitude. The out-plane component of spin polarization is found to vanish zero.

The spin-polarization field of surface state S1 (two concent-
tric rings around $\overline{M}$) reminds one of the “pure” Rashba states at the Au(111) surface, in the sense that $\langle S_k \rangle$ is in-plane and almost perpendicular to $k - k_0$, where $k_0$ is the ring center (here the $\overline{M}$-point; in the Rashba model for Au(111) the $\Gamma$ point). More precisely we observe that $\langle S_k \rangle$ is perpendicular to the group velocity, i.e., $\langle S_k \rangle$ is along the Fermi-surface tangent, as expected from the Rashba model. As for the spin-polarization field of the state $S_2$, first we should remind the reader that $S_2$ merges with the bulk-state continuum (see Fig. 5), excluded from the plot, which leads to the fact that the shown contour in Fig. 5 ends seemingly abruptly. Second, $S_2$ also has a partner with opposite direction of the spin-polarization field, which lies higher in energy (see the band-structure in Fig. 4). $\langle S_k \rangle$ in $S_2$ is also in-plane and perpendicular to the group velocity.

Finally, it should be noted that the magnitude of the spin-polarization fields, $\frac{1}{2} \langle \Psi_k(r) \rangle \sigma \langle \Psi_k(r) \rangle |$ cannot reach the maximal value $\frac{1}{2}$, except perhaps in the pure Rashba model, since an interaction with other states at other energies at the same $k$ via the spin-orbit operator will always be present and will reduce the value. To view this from a different perspective, the states $\Psi_k(r)$ and their linear combination $\Psi_{k_{\max}}(r) = \alpha_k \Psi_k(k) + \beta_k \Psi_k(-k)$ result in a non-collinear spin-density $\frac{1}{2} \Psi_k(r) \sigma \Psi_k(r)$ that can be brought in a diagonal form only in an r-dependent reference frame; but in order to achieve $\langle \langle S_k \rangle \rangle = \frac{1}{2}$, this reference frame would have to be independent of $r$.

IV. ANISOTROPY OF THE ELLIOTT-YAFET PARAMETER AND OF THE SPIN-FLIP SCATTERING RATE OFF ADATOMS

We now examine the anisotropy of the spin-relaxation rate with respect to the polarization direction of the injected spin population (i.e. the SQA $\hat{S}$) relative to the crystallographic axes. For bulk systems we have already discussed the effect in Ref. 14, pointing out that the reduced symmetry of thin films (with respect to the polarization direction of the injected spin population (i.e. the SQA $\hat{S}$) relative to the crystallographic axes. For bulk systems we have already discussed the effect in Ref. 14, pointing out that the reduced symmetry of thin films (with respect to the polarization direction of the injected spin population (i.e. the SQA $\hat{S}$) relative to the crystallographic axes. For bulk systems we have already discussed the effect in Ref. 14, pointing out that the reduced symmetry of thin films (with respect to the polarization direction of the injected spin population (i.e. the SQA $\hat{S}$) relative to the crystallographic axes. For bulk systems we have already discussed the effect in Ref. 14, pointing out that the reduced symmetry of thin films (with respect to the polarization direction of the injected spin population (i.e. the SQA $\hat{S}$) relative to the crystallographic axes. For bulk systems we have already discussed the effect in Ref. 14, pointing out that the reduced symmetry of thin films (with respect to the polarization direction of the injected spin population (i.e. the SQA $\hat{S}$) relative to the crystallographic axes. For bulk systems we have already discussed the effect in Ref. 14, pointing out that the reduced symmetry of thin films (with respect to the polarization direction of the injected spin population (i.e. the SQA $\hat{S}$) relative to the crystallographic axes. For bulk systems we have already discussed the effect in Ref. 14, pointing out that the reduced symmetry of thin films (with respect to the polarization direction of the injected spin population (i.e. the SQA $\hat{S}$) relative to the crystallographic axes. For bulk systems we have already discussed the effect in Ref. 14, pointing out that the reduced symmetry of thin films (with respect to the polarization direction of the injected spin population (i.e. the SQA $\hat{S}$) relative to the crystallographic axes. For bulk systems we have already discussed the effect in Ref. 14, pointing out that the reduced symmetry of thin films (with respect to the polarization direction of the injected spin population (i.e. the SQA $\hat{S}$) relative to the crystallographic axes. For bulk systems we have already discussed the effect in Ref. 14, pointing out that the reduced symmetry of thin films (with respect to the polarization direction of the injected spin population (i.e. the SQA $\hat{S}$) relative to the crystallographic axes. For bulk systems we have already discussed the effect in Ref. 14, pointing out that the reduced symmetry of thin films (with respect to the polarization direction of the injected spin population (i.e. the SQA $\hat{S}$) relative to the crystallographic axes. For bulk systems we have already discussed the effect in Ref. 14, pointing out that the reduced symmetry of thin films (with respect to the polarization direction of the injected spin population (i.e. the SQA $\hat{S}$) relative to the crystallographic axes. For bulk systems we have already discussed the effect in Ref. 14, pointing out that the reduced symmetry of thin films (with respect to the polarization direction of the injected spin population (i.e. the SQA $\hat{S}$) relative to the crystallographic axes. For bulk systems we have already discussed the effect in Ref. 14, pointing out that the reduced symmetry of thin films (with respect to the polarization direction of the injected spin population (i.e. the SQA $\hat{S}$) relative to the crystallographic axes. For bulk systems we have already discussed the effect in Ref. 14, pointing out that the reduced symmetry of thin films (with respect to the polarization direction of the injected spin population (i.e. the SQA $\hat{S}$) relative to the crystallographic axes.
Finally we wish to discuss the physical mechanism of spin relaxation in the presence of Rashba states. In semiconductors or semiconductor heterostructures it is naturally assumed that the spin-polarization fields contribute to spin relaxation via the Dyakonov-Perel mechanism.\footnote{1} There, an electron occupies a state at $k$ that is split in energy by only a little according to an effective Hamiltonian $H = -\frac{1}{2}\Omega_{k} \cdot \sigma$, thus in a semiclassical picture the electron spin precesses around the spin-orbit field $\Omega_{k}$ with a Larmor frequency $|\Omega_{k}|$, losing memory of its original direction before being scattered away (within this effective model the spin polarization field is parallel or antiparallel to the spin-orbit field $\Omega_{k}$). However, for this to happen it must be assumed that the electron wavepacket has an energy spread larger than $|\Omega_{k}|$\footnote{2} This is possible in semiconductors where $|\Omega_{k}|$ is usually small\footnote{3} (of the order of $1 \text{meV}$ or less, depending on temperature, doping concentration, etc.), as usually $|\Omega_{k}| \propto k$ with $k$ very close to the conduction band minimum at $\Gamma$. As opposed to this, in metal surfaces the Rashba splitting $\Delta_{E_{F}}$ of surface states at $E_{F}$ can be large, of the order of $100 \text{meV}$, e.g. $\Delta_{E_{F}} \approx 200 \text{meV}$ in W (Fig. 4), 30$\text{meV}$ in Cu(111)\footnote{4}, and 150$\text{meV}$ in Au(111).\footnote{5} It is unlikely that a coherent wavepacket excited by e.g. an injected spin current or by microwave radiation in CESR should have such a large energy spread, activating the Dyakonov-Perel mechanism, except perhaps if prepared very precisely by an experiment targeting exactly this. Therefore, we consider the Dyakonov-Perel mechanism not applicable in the case of the Rashba surface states of most metals, but we cannot exclude it for special cases e.g. lighter metals with significantly weaker spin-orbit coupling or favorable band structure (e.g. in Ref. 42 we see that Ag(111) shows a splitting of only $\Delta_{E_{F}} = 2 \text{meV}$ due to the shallow surface state).

\begin{figure}[h]
\centering
\includegraphics[width=0.8\textwidth]{fig7.jpg}
\caption{(Color online) Distribution of the spin-mixing parameter $b_{k}^2$ (top) and spin-relaxation rate $T_{1}^{-1}(k)$ (bottom) shown in a color-code (in units of $\text{ps}^{-1}/\text{at}\%$) on the Fermi surface of a 10-layer W(001) film. For the calculation of $T_{1}^{-1}(k)$, scattering off W adatoms was considered. For the calculations shown in the left panels the spin-quantization axis was taken in the [001] direction (i.e., perpendicular to the film), for the calculations shown in the right panels it was taken in the [110] direction (in-plane). The distributions on the Fermi surface are clearly compatible with the specific crystal symmetry operations that either leave $\tilde{s}$ unchanged or result in $\tilde{s} \rightarrow -\tilde{s}$. Especially on the surface states the values of $b_{k}^2$ and $T_{1}^{-1}(k)$ are highest in the regions where the spin-polarization fields (Fig. 3) are perpendicular to $\tilde{s}$.}
\end{figure}

\section{Remarks on the Relaxation Mechanism in the Rashba States}

In summary, we have investigated spin-relaxation physics of W(001) ultrathin films from first principles. We observe that the Elliott–Yafet parameter exhibits an even-odd oscillation with respect to the number of layers of the films, which stems from an even-odd oscillation in the surface electronic structure of the films at and near the Fermi energy. The oscillation is then inherited by the spin-relaxation rate that depends on the Elliott–Yafet parameter.

We have further identified the Rashba character and spin-polarization fields of the surface states and discussed how they contribute to the anisotropy of the spin-relaxation rate with respect to the relative orientation between the spin-quantization axis and the crystallographic directions. The anisotropy values are much higher compared to those in bulk W.

We believe that our findings are not only particular to W(001) free standing films but are more general at least for transition metals in the bcc structure and even when sandwiched between insulators. We base this speculation on three considerations: First, we performed calculations (not pre-
sented in the present paper) of the Elliott-Yafet parameter for Mo(001) films in the bcc structure and found basically the same oscillatory effect. Second, the existence of surface states is, in general, closely connected to the crystal structure; all bcc transition metals will show a dip in the density of states at the center of the d-band and in all cases the breaking of translational symmetry at the (001) surface will produce surface states of the character found here within the gap of the surface-projected bulk band-structure. Third, the mechanism just stated is expected to produce interface states in the case that the film is in contact with an insulator, even if the details of the interface band structure can be more complicated in this case.

As an outlook we believe that it is worthwhile to investigate these effects in a broader family of ultrathin films. Such investigations are in progress and will be reported in a future publication.

**Acknowledgments**

We would like to thank Gustav Bihlmayer for discussions on the Rashba effect and Martin Gradhand for discussions on the spin-flip scattering in films. This work was financially supported by the MO 1731/3-1 project and SPP 1538 SpinCaT programme of the Deutsche Forschungsgemeinschaft, and the HGF-YIG NG-513 project of the Helmholtz Gemeinschaft.
