ABSTRACT

We reproduce the mid-infrared to radio galaxy counts with a new empirical model based on our current understanding of the evolution of main-sequence (MS) and starburst (SB) galaxies. We rely on a simple spectral energy distribution (SED) library based on Herschel observations: a single SED for the MS and another one for SB, getting warmer with redshift. Our model is able to reproduce recent measurements of galaxy counts performed with Herschel, including counts per redshift slice. This agreement demonstrates the power of our 2-Star-Formation Modes (2SFM) decomposition in describing the statistical properties of infrared sources and their evolution with cosmic time. We discuss the relative contribution of MS and SB galaxies to the number counts at various wavelengths and flux densities. We also show that MS galaxies are responsible for a bump in the 1.4 GHz radio counts around 50 μJy. Material of the model (predictions, SED library, mock catalogs, etc.) is available online.

Key words: galaxies: evolution – galaxies: star formation – galaxies: statistics – infrared: galaxies – submillimeter: galaxies

Online-only material: color figures

1. INTRODUCTION

Recent observational studies have shown that two distinct star-forming (SF) mechanisms are required to describe the SF galaxy population. The so-called SF main sequence (MS) is composed of secularly evolving galaxies that display a tight correlation between stellar mass ($M_*$) and star formation rate (SFR) at a given redshift (e.g., Elbaz et al. 2007; Noeske et al. 2007; Daddi et al. 2007). This population accounts for ~85% of the star formation rate density (SFRD) in the universe (Rodighiero et al. 2011; Sargent et al. 2012) at $z < 2$. The rest of the star formation budget is provided by starbursts (SBs), i.e., galaxies with very high specific star formation rates ($sSFRs = \text{SFR}/M_*$), probably induced by recent mergers (e.g., Elbaz et al. 2011; Rodighiero et al. 2011). Recently, Sargent et al. (2012, S12 hereafter) showed that infrared (IR) luminosity functions (LFs) can be reproduced by jointly considering the mass function of SF galaxies (SFMF), the evolution of the sSFR of MS galaxies, and its distribution at fixed $M_*$, with a separate contribution from MS and SB galaxies.

Wavelength-dependent galaxy number counts are an additional, important constraint for evolutionary models of infrared galaxies. While purely semi-analytical models (e.g., Lacey et al. 2010; Somerville et al. 2012) struggle to reproduce infrared (IR) number counts, phenomenological or hybrid models (e.g., Béthermin et al. 2011; Gruppioni et al. 2011; Rahmati & van der Werf 2011; Lapi et al. 2011) fare better but are in general descriptive and use an evolution of the LF which is not motivated by physical principles. However, these recent models which reproduce the total counts passably are excluded at $> 3\sigma$ by the recent Herschel measurements of counts per redshift slice (Berta et al. 2011; Béthermin et al. 2012b). This shows how important redshift-dependent constraints are to accurately model the evolution of galaxies, and motivates the development of a new generation of models.

We present a new model of IR galaxy counts which builds on the 2-Star-Formation-Mode framework (2SFM) S12 introduced. This fiducial model is intuitive and based on our current observational knowledge of the evolution of MS and SB galaxies. All model parameters are constrained by external data sets and require no additional fine tuning. We assume a Salpeter initial mass function and a WMAP-7 cosmology.

2. MAIN INGREDIENTS

Our model is based on four main ingredients, which are sufficient to reach a good agreement with IR source counts (see Section 4 and gray line in Figure 3):

1. evolution of the MS with redshift,
2. decomposition of the sSFR distribution at fixed $M_*$ into MS and SB modes,
3. evolution of the SFMF with redshift,
4. spectral energy distribution (SED) libraries for MS and SB galaxies.
Additional ingredients, which are of lesser importance, are presented in Section 3.

2.1. SFR Distribution

A key ingredient of the S12 approach is the probability distribution of sSFR at fixed $M_\star$ for SF galaxies based on observations presented in Rodighiero et al. (2011). It is parameterized as a double log-normal decomposition of MS and SB:

$$
\begin{aligned}
    \rho(\text{log}(sSFR)) &\propto \exp\left( -\frac{(\text{log}(sSFR)-\text{log}(sSFR_{\text{MS}}))^2}{2\sigma_{\text{MS}}^2} \right) \\
    + r_{\text{SB}} \times \exp\left( -\frac{(\text{log}(sSFR)-\text{log}(sSFR_{\text{MS}})-B_{\text{SB}})^2}{2\sigma_{\text{SB}}^2} \right),
\end{aligned}
$$

where $\sigma_{\text{MS}}$ and $\sigma_{\text{SB}}$ are the dispersion in the sSFR of the MS and the SB populations. $B_{\text{SB}}$ is the average sSFR boost for SB galaxies. We assume that these three parameters do not evolve with $M_\star$ and redshift, as suggested by S12 who reproduce the $z \sim 0$ IR LF under these assumptions and with the distribution calibrated at $z \sim 2$ (see Table 1 for parameter values adopted). $sSFR_{\text{MS}}$ varies with $M_\star$ and redshift according to

$$
sSFR_{\text{MS}}(z, M_\star) = sSFR_{\text{MS},0} \times \left( \frac{M_\star}{10^{11} M_\odot} \right)^{\beta_{\text{MS}}} \times (1 + \min(z, z_{\text{evo}}))^{\gamma_{\text{MS}}},
$$

where $sSFR_{\text{MS},0}$ is the sSFR at $z = 0$ for $M_\star = 10^{11} M_\odot$ and $\beta_{\text{MS}}$ parameterizes the dependence of sSFR on $M_\star$. $\gamma_{\text{MS}}$ describes the evolution of the normalization of the MS out to redshift $z_{\text{evo}} = 2.5$ where this evolution flattens according to observations (e.g., González et al. 2010). The values of these parameters, chosen based on measurements summarized in Figures 1(b) and (c), are listed in Table 1. S12 also present evidence for a weak redshift evolution of $r_{\text{SB}}$, the relative amplitude of SB sSFR log-normal distribution compared to MS one (or, equivalently, of the relative SB contribution to the SFRD, see Figure 1(d)), in agreement with the model of Hopkins et al. (2010). Here we define the redshift evolution of $r_{\text{SB}}$ as

$$
r_{\text{SB}}(z) = r_{\text{SB},0} \times (1 + \min(z, z_{\text{SB}}))^{\gamma_{\text{SB}}}, \text{ where } z_{\text{SB}} = 1,
$$

in order to broadly reproduce the trends suggested by these two studies (see Figure 1(d)). The impact of this evolving $r_{\text{SB}}$ is negligible, barring a $\sim 20\%$ decrease of 70 $\mu$m counts compared to a constant $r_{\text{SB}}$.

Another important ingredient of our model is the evolution of the SFMF. Observations are well described by a Schechter function:

$$
\phi = \frac{dN}{d\text{log}(M_\star)} = \phi_b(z) \times \left( \frac{M_\star}{M_b} \right)^{-\alpha_{\text{SF}}} \times \exp\left( -\frac{M_\star}{M_b} \right) \times \frac{M_\star}{M_b} \ln(10),
$$

with a redshift-invariant characteristic mass $M_b$ and faint-end slope $\alpha_{\text{SF}}$, in keeping with Peng et al. (2010). $\phi_b$, the characteristic density, is constant between $z = 0$ and $z = 1$ but decreases at $z > 1$ as

$$
\text{log}(\phi_b) = \text{log}(\phi_b)(z < 1) + \gamma_{\text{SFMF}}(1-z).
$$

The fiducial values (chosen from Figure 1(a)) of the MF-related parameters are also listed in Table 1.

The star formation history implied by our evolutionary formalism is shown in Figure 1(e). The SFRD density increases from $z = 0$ to 1, flattens between $z = 1$ and $z = z_{\text{evo}} = 2.5$, and decreases with redshift at $z > z_{\text{evo}}$, matching the infrared measurements of Magnelli et al. (2011) and Rodighiero et al.
(2011), the radio measurements of Karim et al. (2011), and the optical measurements of Bouwens et al. (2007) at high redshift. The SFMF is quite uncertain at \( z > 4 \), but this has little impact on the counts. In our model, the SFRD is dominated by MS galaxies at all redshifts.

2.2. SEDs

We use a characteristic IR SED template for MS and SB based on fits of Draine & Li (2007) models to Herschel observations of distant galaxies as presented in Magdis et al. (2012, hereafter M12). While conceptually similar to Elbaz et al. (2011), however, our templates evolve with redshift following the finding of M12 that the mean radiation field \( \langle U \rangle \) (which correlates with dust temperature) is more intense at high redshift:

\[
\langle U \rangle = \langle U \rangle_0 \times (1 + \min(z, z(U)))^{\gamma_U}.
\]

Here, \( \langle U \rangle_0 \) is the mean radiation field in local MS galaxies, \( \gamma_U \) is a parameter determining its evolution with redshift, and \( z(U) \) is the redshift where \( \langle U \rangle \) flattens. This evolution is different in MS and SB galaxies (see Figure 2 and Table 1). This evolution is caused by the evolution of SF efficiency and metallicity with redshift (M12), and is required to reproduce source counts. For example, if we used the \( z = 1 \) (\( z = 0 \)) MS template for all redshifts, we would overestimate the counts by a factor of 2 (1) at 70 \( \mu \)m and 2 (10) at 1.1 mm. For reference, if we use the MS and SB templates of Elbaz et al. (2011), we overpredict the millimeter counts by a factor of 10 at all fluxes and underpredict the 100 \( \mu \)m counts by \( \sim 30\% \). To reproduce the 24 \( \mu \)m counts, it is crucial to use distinct SB templates with less mid-IR emission than in MS galaxies. The SEDs of MS and SB galaxies used in our model are shown in Figure 2. We introduce a relative dispersion on \( \langle U \rangle \) of 0.2 dex for both MS and SB (M12), which has little impact on the counts (\( < 10\% \)), except in the millimeter domain (+20\%). In this approach, the increasing mean dust temperature with infrared luminosity \( (L_{IR}) \) at a given redshift is caused by a higher fraction of SB galaxies at higher \( L_{IR} \).

3. REFINEMENTS

3.1. Dust Attenuation

To reproduce IR number counts we have to link SFR and \( L_{IR} \). For obscured SF galaxies, the bulk of the UV light emitted by young stars is absorbed by dust and re-emitted in the IR (SFR\( IR/L_{IR} = K = 1.7 \times 10^{-10} \ M_\odot \ yr^{-1} L_\odot^{-1}; \) Kennicutt 1998). In less massive galaxies, the attenuation is smaller and a significant part of the SF can be detected in UV. The total star formation can then be divided into an uncorrected UV and an IR component (SFR = SFR\( UV + \) SFR\( IR \)). The mean ratio between these two components, \( r_{1500} \), varies with \( M_\star \). Here, we apply the relation of Pannella et al. (2009):

\[
r_{1500} = 2.5 \log \left( \frac{\text{SFR}_{IR}}{\text{SFR}_{UV}} \right) = 4.07 \times \log \left( \frac{M_\star}{M_\odot} \right) - 39.32, \tag{7}
\]

and assume redshift invariance, as suggested by Sobral et al. (2012) and M. Pannella et al. (in preparation). The IR luminosity
of the galaxies, \( L_{\text{IR}} \), is thus given by

\[
L_{\text{IR}} = \frac{\text{SFR}_{\text{IR}}}{K} = \frac{\text{SFR}}{K} \times \frac{10^{0.4 \times r_{\text{IR}}}}{1 + 10^{0.4 \times r_{\text{IR}}}} = \frac{\text{SFR}}{K} \times f^\text{IR}_{\text{SF}}(M_*) , \tag{8}
\]

where \( f^\text{IR}_{\text{SF}}(M_*) = \text{SFR}_{\text{IR}}/\text{SFR} \) goes to 0 at low mass and 1 at high mass. This correction implies a flatter IR LF at the faint end as compared to the SFMF at the low-mass end and prevents an excess in the counts at faint flux densities. Although a small part of the IR emission is due to dust heated by old stars, especially at low-z, we consistently reproduce \( z = 0-2 \) IR LF (S12).

### 3.2. AGN Contribution

Active galactic nucleus (AGN) activity is potentially important when modeling mid-IR counts. We statistically associate an AGN contribution, represented by the average intrinsic SED template of Mullaney et al. (2011), with each galaxy based on its \( L_{\text{IR}} \). Aird et al. (2012) showed that the Eddington ratio \( r_{\text{Edd}} \) (bolometric luminosity \( L^\text{bol}_{\text{AGN}} \) over Eddington luminosity) of AGNs at \( z < 1 \) follows a power-law probability distribution function (PDF) with redshift-dependent normalization. Based on the results of Mullaney et al. (2012)—who report a coincident cosmological evolution of the averages of specific black hole (BH) growth (\( M_{\text{BH}}/M_\odot \), where \( M_{\text{BH}} \) is BH mass) and sSFR over \( 0.5 < z < 2.5 \), a fact that implies constant \( M_{\text{BH}}/M_* \) ratios—we can express the Aird et al. (2012) results in terms of a distribution of ratios of bolometric luminosities \( r^\text{AGN}_{\text{IR}} = L^\text{AGN}_{\text{IR}}/L^\text{SF}_{\text{IR}} \) from AGN and SF with redshift-independent normalization:

\[
p(r_{\text{Edd}}) = C(z) \times r_{\text{Edd}}^{\text{bol}} \rightarrow p(r_{\text{Edd}}) = A_{\text{AGN}} \times r_{\text{AGN}}^{\text{bol}}. \tag{9}
\]

where we recall that

\[
\frac{\dot{M}_{\text{BH}}}{M_\odot} \propto \frac{L^\text{bol}_{\text{AGN}}}{M_*} \propto \frac{L^\text{AGN}_{\text{IR}}}{(L^\text{SF}_{\text{IR}})^{\beta_{\text{AGN}}}} \approx \frac{L^\text{AGN}_{\text{IR}}}{L^\text{SF}_{\text{IR}}} \tag{10}
\]

The last step uses the \( M_* \)–SFR correlation. \( \beta_{\text{AGN}} = -0.7 \) comes from Aird et al. (2012). \( A_{\text{AGN}} \) is based on the normalization of the Aird et al. (2012) relation and includes a scaling factor for the conversion between \( r_{\text{Edd}} \) and \( r^\text{AGN}_{\text{bol}} \) PDFs. This scaling relation assumes a mean ratio between BH and stellar mass of 0.0015 (Mullaney et al. 2012), plus a mean ratio between \( L^\text{bol}_{\text{AGN}} \) and \( L^\text{bol}_{\text{SF}} \) calibrated from Mullaney et al. (2011), Lutz et al. (2004), and Vasudevan & Fabian (2007). In order to normalize this PDF, we place a cut at \( \lambda_{\text{Edd}} = 1 \) and choose a lower bound such that \( \int p(r_{\text{AGN}}) dr_{\text{AGN}} = 1 \). We emphasize that Equation (9) implies a correlation between AGN and SF activity only in an average sense, while preserving a large dispersion for individual objects consistent with observations. Full details of our AGN treatment will be presented in a future paper. The AGN contribution is significant (>10%) only at 24 \( \mu \)m above 3 mJy (see Figure 3) and negligible at longer wavelengths (<2%).

### 3.3. Magnification Caused by Strong Lensing

Having computed the IR LF, split into MS and SB contribution as in S12, we include the effect of the strong \( (\mu > 2) \) lensing (Negrello et al. 2007, 2010) on these two LFs:

\[
\frac{d^2 N}{d \log L_{\text{IR}} dV} |_{\text{lensed}} = \int_{\mu=2}^{\infty} \frac{d P(\mu, z)}{d \log \mu} \frac{d^2 N}{d \log L_{\text{IR}} dV} |_{\text{initial}} d \log \mu , \tag{11}
\]

where \( \mu \) is the magnification, \( (d P/d \log \mu) \) is the magnification PDF in the Hezaveh & Holder (2011) model, and \( (d^2 N/d \log L_{\text{IR}} dV) \) is the LF. These lensed sources contribute ~20% to (sub-)millimeter counts around 100 mJy.

### 4. RESULTS

Number counts are computed according to

\[
\frac{d^2 N}{d S d z}(S, z, \lambda) = \sum_{\text{type} = \{\text{MS, SB}\}} \int_{U} \int_{r^\text{AGN}} d r_{\text{AGN}} d \langle U \rangle \times \frac{d^2 N_{\text{type}}}{d L_{\text{IR}} d V} \times 1 L_\odot \times \frac{S_{\text{norm}}(\lambda, z) \times r_{\text{AGN}} \times S_{\text{AGN}}(z, \lambda)}{S_{\text{norm}}(z, \lambda) + r_{\text{AGN}} \times S_{\text{AGN}}(z, \lambda)} \times 1 L_\odot \times p(r_{\text{AGN}}) p(U) |_{z, \lambda} . \tag{12}
\]
Figure 3. Number counts from 24 \( \mu m \) to 1.1 mm. Solid line—total counts predicted by the model; gray line—counts predicted by the simplified model (without refinements discussed in Section 3); dotted line—MS contribution; short-dashed line—SB contribution; dot-dashed line—lensed sources; triple-dot-dashed line—difference between counts with and without AGN contribution. At 1.4 GHz, we also plot the model of AGN-driven radio sources of Massardi et al. (2010; long-dashed line) and combine it with our model of SF galaxies. Data points—Béthermin et al. (2010a; red points at 24, 70, and 160 \( \mu m \)), Berta et al. (2011; blue points at 70, 100, and 160 \( \mu m \)), Oliver et al. (2010; blue points at 250, 350, and 500 \( \mu m \)), Glenn et al. (2010; green points at 250, 350, and 500 \( \mu m \)), Clements et al. (2010; yellow points at 250, 350, and 500 \( \mu m \)), Béthermin et al. (2012b; red points at 1.1 mm), and Vernstrom et al. (2011; compilation of 1.4 GHz radio counts). Black dots—contribution of lensed galaxies at 350 \( \mu m \) measured by González-Nuevo et al. (2012).

Here \( S_{\text{norm}}^{\text{type}}(U) \) is the flux of an \( L_{\text{IR}} = 1 L_{\odot} \) source of a given type (MS or SB) and a given \( U \) in a given filter. \( S_{\text{norm}}^{\text{AGN}} \) is the same quantity, computed using the Mullaney et al. (2011) AGN template. Note that the filter shape is taken into account for the calculation of \( S_{\nu} \). \( p(V_{\text{AGN}}) \) is provided by Equation (9) and \( p((U)) \) is a log-normal distribution with a width of 0.2 dex (see Section 2).

We compare the predictions of our model with measurements of differential galaxy counts from 24 \( \mu m \) to 1.1 mm (see Figure 3). Spitzer and Herschel counts are well reproduced, showing the effectiveness of our new approach. Note, however, a 10%–20% (~2\( \sigma \)) excess at 24 \( \mu m \) between 400 mJy and 2 mJy, and a ~20% (~2\( \sigma \)) excess at the faint end at 70 and 160 \( \mu m \) (<1 mJy and <5 mJy, respectively). The BLAST and SPIRE counts at 250, 350, and 500 \( \mu m \) are globally well reproduced. Nevertheless, the model slightly overpredicts the three last points of Béthermin et al. (2012b; in red). As discussed by these authors, this could be related to an underdensity in GOODS-N. The contribution of lensed sources broadly agrees with the measurements of González-Nuevo et al. (2012) at 350 \( \mu m \). At 1.1 mm, our model nicely agrees with the combined number counts of Scott et al. (2012),10 except for the faintest point, originating from 1\( \sigma –2\sigma \) sources and potentially poorly de-biased.

10 The counts showed in Figure 3 are corrected for the bias found in their simulation.
Since the LF evolution and number counts may be degenerate (Béthermin et al. 2012b), galaxy counts split per redshift provide a powerful test of the validity of our model (note that S12 demonstrated that bolometric IR LF are reproduced at \( z < 2.5 \)). This observable is close to the monochromatic LF, but requires fewer corrections (\( K \)-corrections, \( V_{\text{max}} \)) which could bias the results (possible biases from photometric redshifts and source identification are discussed in Berta et al. 2011 and Béthermin et al. 2012b). The comparison between our model and observations (Figure 4) reveals a good overall agreement between predictions and data. However, we slightly overpredict the counts around 500 \( \mu \)Jy between \( z = 0.5 \) and \( z = 2 \) at 24 \( \mu \)m. It could be due to a slight excess of polycyclic aromatic hydrocarbon features around 15 \( \mu \)m in the SB templates. We also underpredict the counts at 100 and 160 \( \mu \)m by 1\(\sigma\)–2\(\sigma\), probably due to a slight lack of warm dust in the SED templates. Finally, our model overpredicts by \( \sim 3\sigma \) the \( z > 2 \) counts in the 2–6 mJy range. As explained in the previous paragraph, this could be due to cosmic variance, as these points rely exclusively on GOODS-N.

By distinguishing between MS and SB activity, the 2SFM framework allows us to explore selection biases toward MS or SB objects in surveys probing various wavelengths and flux density regimes. MS galaxies (dotted line in Figure 3) dominate the number counts at all flux densities and all wavelengths. However, the relative contribution of SBs varies a lot with flux density and wavelength and is important (\( \sim 30\% \)) around 30 mJy at 70 \( \mu \)m and 50 mJy at 350 and 500 \( \mu \)m. The relative contribution of SB is very sensitive to the evolution of their SED, which is few constrained by the data. If \( \langle U \rangle \) did not evolve with redshift, SBs would dominate around 100 mJy at 350 and 500 \( \mu \)m and at flux densities larger than 8 mJy at 1.1 mm.

Finally, by assuming a non-evolving IR-radio correlation \( (q_{\text{TIR}} = \log((L_{\text{TIR}}/3.75 \times 10^{12} \text{W}) \times (W \text{Hz}^{-1}/L_{1.4 \text{GHz}})) = 2.64) \) out to high redshift (e.g., Sargent et al. 2010) and a synchrotron spectral slope \( \alpha = 0.8 \) (\( S_{\nu} \propto \nu^{-\alpha} \)), we also investigate the contribution of SF galaxies to radio source counts at 1.4 GHz (see Figure 3). We combined our model for SF objects with the model of AGN-driven radio sources of Massardi et al. (2010). The result agrees with the compilation of Vernstrom et al. (2011; see Figure 3). According to our model, the 1.4 GHz counts are dominated by SF objects below 200 \( \mu \)Jy, in agreement with the observations of, e.g., Seymour et al. (2008). We predict the presence of a bump in the Euclidean-normalized radio counts around 40 \( \mu \)Jy which is essentially due to MS galaxies.

5. CONCLUSION

Our model based on the main assumption of two SF modes (MS and SB) is able to accurately reproduce the emission of galaxies integrated over most of the Hubble time as probed by galaxy counts from the mid-IR to radio wavelengths. This model contains two main ingredients: the evolution of MS and SB galaxies based on the S12 formalism and a new library of MS and SB SEDs derived from Herschel observations (M12). Despite its simplicity, our model provides one of the best fits achieved so far to the number counts, including counts per redshift slice in the SPIRE bands, which were poorly reproduced by the previous generation of models. All these results were obtained without any arbitrary tuning of parameters that are not constrained by observations, contrary to most previous models. The decomposition into two modes of SF (2SFM), i.e., MS and SB, associated with two different families of SEDs, is thus a very powerful framework to statistically describe the dust emission of galaxies.

Figure 4. Normalized number counts per redshift slice, compared to model predictions. Data from Le Floc’h et al. (2009; 24 \( \mu \)m), Berta et al. (2011; 70, 100, 160 \( \mu \)m), and Béthermin et al. (2012b; 250, 350, 500 \( \mu \)m). For clarity, a redshift-dependent vertical offset has been applied to model and data. Dashed line—contribution of SB. (A color version of this figure is available in the online journal.)
across cosmic time. In addition, we present a new stochastic AGN treatment, and also found that MS galaxies are responsible for a bump in the 1.4 GHz radio counts around 50 μJy.

This model can be combined with halo models assuming a link between SFR, $M_*$, and halo mass (e.g., Béthermin et al. 2012a; Wang et al. 2012) to interpret the clustering of infrared galaxies and the fluctuation of the cosmic infrared background (e.g., Planck Collaboration et al. 2011). Finally, this model and its future extensions will provide predictions for the next generation of IR, millimeter, and radio surveys, and, in particular, to anticipate which galaxy populations will be preferentially detected, depending on the survey strategy adopted.

Material of the model (predictions, SED library, mock catalogs, etc.) is available online.
