(Dated: January 14, 2013)

A superconducting quantum interference device (SQUID) was prepared on a micron-sized single crystal using a selected growth domain of a thin film of CeCoIn$_5$ grown by molecular beam epitaxy. SQUID voltage oscillations of good quality were obtained as well as interference effects stemming from the individual Josephson microbridges. The transport characteristics in the superconducting state exhibited several peculiarities which we ascribe to the periodic motion of vortices in the microbridges. The temperature dependence of the Josephson critical current shows good correspondence to the Ambegaokar-Baratoff relation, expected for the ideal Josephson junction. The results indicate a promising pathway to identify the type of order parameter in CeCoIn$_5$ by means of phase-sensitive measurements on microbridges.

I. INTRODUCTION

Heavy fermion (HF) systems are a class of intermetallic compounds in which electronic correlation effects are particularly pronounced. In HF materials the correlation effects manifest themselves as a strong increase of the effective mass of the charge carriers at low temperatures accompanied with a crossover to the behavior of a Landau Fermi liquid. Hybridization between originally localized f-states and the itinerant band states of these mainly Ce- and U-based compounds is causing this behavior. In special cases, either by chemical substitution or by external stimuli, such as applying pressure or a magnetic field, a sub-class of the HF system can be tuned into a quantum critical state. In this state, characterized by the shift of a magnetic phase transition to $T = 0K$, magnetic fluctuations exert their influence not only at $T = 0K$ but also at higher temperatures and cause strong deviations from Landau’s Fermi liquid behavior. Consequently, these materials are said to behave as non-Fermi liquids. In these non-Fermi liquids the low lying charge excitations cannot be simply described as quasi-particle excitations. Nevertheless, superconducting (SC) condensates can form in the non-Fermi liquid state which is, e.g., the case for CeCoIn$_5$. The nature of the SC state in this HF material is therefore particularly interesting. Several experiments, such as magnetic field dependent heat conductivity, specific heat, and also point contact spectroscopy, have provided evidence for a $d_{x^2-y^2}$ order parameter. As has been demonstrated for selected high temperature superconductors, phase sensitive experiments employing the Josephson effect can be very helpful in elucidating the order parameter type in a very direct way. This pathway for HF superconductors is, however, difficult to follow. It mainly relies on the availability of epitaxial thin films. For selected materials efforts in this direction have been successful and have eventually led to well characterized tunnel junctions. For CeCoIn$_5$, however, attempts by several groups have so far not led to epitaxial growth. As a possible way out of this difficulty we have previously developed a technique for addressing individual growth domains or microcrystals in c-axis oriented thin films of CeCoIn$_5$ by combining focused ion beam (FIB) etching and focused particle beam induced deposition with appropriate precursors. In this work we take advantage of the de-wetting tendency during early stages of CeCoIn$_5$ thin film growth on a-plane sapphire for selecting an individual growth domain or microcrystal of about two micrometer lateral dimensions suitable for the fabrication of a microbridge-based SQUID. Both, the SQUID loop and the individual microbridges exhibit well-defined voltage modulations in an external magnetic field. The microbridges critical dc Josephson current is in good agreement with the Ambegaokar-Baratoff (AB) model. Furthermore, in the dynamic resistance we see clear signatures of periodic vortex motion in the microbridges. These results point towards a very promising approach for phase sensitive studies in HF superconductors.

II. PREPARATIONS

The CeCoIn$_5$ thin film was grown on a 10 × 10 mm$^2$ a-plane α-Al$_2$O$_3$ substrate by molecular beam epitaxy method with the growth details and a typical surface morphology reported earlier. The thin film was pre-patterned with conventional ultra violet photolithography and ion beam etching. The micro-structuring (see Fig. 1 (a) and (b)) was performed with FIB milling in an FEI Nova NanoLab 600 dual beam scanning electron microscope (SEM). The outer electrodes (not shown in the figure) were metallic W-composite leads prepared by FIB induced deposition using W(CO)$_6$ as precursor gas. A SEM micrograph of the prepared SQUID is shown in Fig. 1c and a detailed view of one of the microbridges in the inset. The electrical measurements were performed in a $^3$He cryostat employing a four-probe method and a standard differential resistance measurement technique using current modulation.

III. MEASUREMENTS

The four-probe resistance of the loop was measured during cool down at a small constant current $I$, and...
its low temperature region is shown in the inset of Fig. 2. The complete curve shows the typical behavior for CeCoIn$_5$, as was reported for microcrystal measurements before. The residual resistance ratio $R_{300\mathrm{K}}/R_{\mathrm{above\:T_c}}$ was found to be 2.9, and is slightly better than in the aforementioned work. However, this value is still small when compared to the value for bulk crystals, which indicates a lower crystal quality for this microcrystal. The resistivity at $2.5\mathrm{K}$ is also slightly larger than was reported for single crystal. The onset of superconductivity is found at $2.0\mathrm{K}$, somewhat lower than that of a bulk crystal. Another smooth transition is found at around $1.5\mathrm{K}$, which we attribute to the Josephson coupling temperature $T_J$. This transition we ascribe to the SC transition in the bridges, and the local $T_c$ being reduced by the FIB milling process. Also, an important feature is the finite resistance $R_0 \approx 0.07\Omega$ (also when $I \to 0$) at the lowest temperature, which we explain as follows. Thermally activated processes may fundamentally modify the voltage-to-current $V-I$ relation of a Josephson junction. In particular, as was shown by Ambegaokar and Halperin, there is always a finite resistance even below the Josephson critical current $I_c$. This may be viewed as an overdamped junction, i.e. a junction for which the McCumber parameter is small, which is expected to be the case for microbridges.

The theoretical analysis of bridges whose dimensions are large compared to the Ginsburg-Landau (GL) coherence length $\xi$ is difficult. For large ratios of $W/\xi$ and $L/\xi$ the bridge leaves the regime of the ‘ideal’ Josephson behavior and enters the Abricosov vortex motion regime, as was pointed out by Likharev. As a result, essential characteristics of the bridge are modified, such as the shape of SQUID voltage modulations or the dependence $I_c(T)$. The dimensions of our bridges when compared with $\xi_{\mathrm{CeCoIn}_5} \approx 5\mu\mathrm{m}$ make both ratios $W/\xi \approx 18$ and $L/\xi \approx 50$ large.

In the main part of Fig. 2 we show a set of measured dynamic resistance curves as a function of current plotted for selected temperatures. The curves measured above $T_c$ show an anomalous background resistance, visible up to $10\mathrm{K}$, out of which evolves the SC state. This nonlinearity, which we do not attribute to self heating effects, will be addressed in a separate publication. Signatures of superconductivity become evident on top of the background anomaly at about $2.0\mathrm{K}$ and become more pronounced as the temperature decreases. At temperatures below $T_J$ the curves develop additional features, which we marked by arrows on the lowest curve.

The inset in Fig. 3 shows typical measured SQUID voltage oscillations as a function of an externally applied magnetic field. The oscillations are well reproducible and of sine-like shape without asymmetries. The period of the measured oscillations corresponds to one flux quantum $\Phi_0 = h/2e$ over the averaged loop area with excellent agreement. Occasionally, the oscillations become phase-shifted by a random amount. Since the oscillations are a measure of the SC phase difference between the two SC arms modulated by an external magnetic field, we attribute these phase slips to randomly trapped flux. The main part of Fig. 3 shows a long period modulation superimposed with the SQUID modulations, which appear as a band due to the scale. We ascribe them to the Josephson behavior.
son modulations of the two individual bridges. These oscillations are also affected by random phase slips. Their perturbed periodicity might be caused by interference effects between both bridges, since they are coupled by the SC wave function in the arms. A rough estimate of the period for these oscillations gives 10 mT, and according to \( s = \Phi_0/B \) implies that the effective dimensions of each bridge extend into each SC bank by about 200 nm, which compares favorably with the London penetration depth \( \lambda_L \) for CeCoIn\(_5\).

\[ V_0 = \frac{1}{2\sqrt{2}} \frac{4\pi}{\mu_0 a} \frac{d^3}{\alpha \sqrt{\lambda_{eff}^2}} \frac{1}{\varepsilon^2 \eta} \]

where \( \lambda_{eff} \) is the effective penetration depth, which we take as \( \lambda_L \), since \( \lambda_L \approx d \) and the correction is small. We attribute the smoothed peaks marked with arrows in Fig. 2 each to a new number of vortex pairs moving simultaneously in the bridge. They appear, as expected, just above \( I_c \). Three corresponding peaks are well resolved, which in our case implies that the strong repulsion between neighboring vortices of equal helicity limits considerably their number. This is very probable because the average inter-vortex distance \( \alpha/3 \) is comparable with the vortex radius. Also, large values of \( \lambda_L \approx 235 \text{nm} \) for CeCoIn\(_5\) do increase the inter-vortex repulsive coupling. The peaks are not equidistant with current, which is also expected from the AL model, but the voltage peaks are equidistant with a period of about 125 \( \mu \text{V} \) with good accuracy. This periodicity we ascribe to \( V_0 \) as predicted by the AL model. One may obtain the viscosity coefficient \( \eta \) from Eq. (1). Using \( \lambda_L = 235 \text{nm} \), the approximate thickness in the bridge as \( d/2 \approx 150 \text{nm} \), and \( \xi = 10 \text{nm} \) we find \( \eta \approx 5.0 \times 10^{-15} (AV^2 s^{-2} m^{-2}) \). The agreement with the Bardeen-Stephen theory is good, which gives \( \eta \approx 2.6 \times 10^{-15} (AV^2 s^{-2} m^{-2}) \) using \( \xi = 10 \text{nm} \) and the normal state resistivity \( \rho_n = 4.0 \times 10^{-7} \Omega m \).

A temperature dependence of the reduced Josephson critical current \( I_c \) for the two bridges is shown in Fig. 4. The dots represent measured data and the solid lines are theoretical curves for several cases using the measured \( T_J \) and the normal state resistance \( \rho_n \). It is clear that the AB model fits the data well, although \( R_n = 68 \Omega \) has

\[ F_L = \text{the Lorentz force due to the interaction with current } J, \ F_s = \text{the interaction with the edge, and } F_{vv} = \text{the vortex-vortex interaction term. At low } T \text{ a vortex remains pinned to the edge due to } F_s \text{ as long as the counteracting Lorentz force is } F_L \leq F_s \text{. Neglecting the } F_{vv} \text{ term when the number of vortices in the bridge is small, one may derive the current at which } F_L = F_s \text{ as } J_L \approx J_0 \sqrt{a/2\xi}, \text{ where } J_0 = e^2 h/8e \lambda_L^2 \text{.} \]
FIG. 4. The reduced Josephson critical current for an individual microbridge plotted versus temperature. Circles represent the measured data. Solid curves are calculated for: (AB)-Ambegaokar-Baratoff, Kulik-Omel’yanchuk models for diffusive regime (KO-I), and for ballistic regime (KO-II). $T_J$ denote the Josephson coupling temperature. The measured value of the normal state resistance $R_n \approx 42\Omega$, while effective one used for the AB fit is $68\Omega$. The measured $I_c$ at the lowest temperature is $\approx 5.2\mu A$ to be used instead of the measured value of $42\Omega$. This is not unexpected. On the one hand, the AB fit tends to overestimate the value of $I_c$ for $L > \xi$, since $R_n$ growth linearly with $L$ but the GL order parameter in the middle of the bridge falls off exponentially. On the other hand, the AB model is derived for tunnel junctions, that is $L \ll \xi$ and with no scattering within the barrier. In contradistinction, models derived for microconstrictions, such as that by Kulik and Omel’yanchuk, in the dirty or clean limit or Ishii’s model for long bridges do not fit the data. Additionally, the shape of the voltage modulations are not asymmetric, as expected in these models. We have to state that the observed $I_c(T)$ dependence does not follow the probably expected behavior theoretically predicted for microbridges in the dirty or clean limit. These models do not take a possible influence of Andreev bound states\cite{31} for a $d$-wave order parameter into account, which may be one reason for this discrepancy.

V. CONCLUSIONS

The clean SQUID characteristics observed in this work on selected CeCoIn$_5$ microcrystals allow for two main conclusions. First, the fact that the micro-patterning approach used here is not detrimental to the superconducting state in CeCoIn$_5$ indicates a certain robustness of this state. Considering, as a rule, the high sensitivity of the superconducting properties in other heavy-fermion superconductors, this may point toward an enhanced stability of the superconducting state when formed from a non-Fermi liquid. Second, the approach followed here provides junctions with rather close-to-ideal characteristics, which is promising with regard to utilizing other microbridge geometries. These geometries, such as recently proposed by Gumann and Schopohl\cite{32} or also a $\pi$-junction structure, which can e.g. be formed by the combination of a conventional SC lead prepared by focused ion beam induced deposition using the W(CO)$_6$ precursor with a CeCoIn$_5$ microcrystal, can provide phase-sensitive information about the superconducting state in CeCoIn$_5$. Work along these lines is in progress.
