The study of the primary metabolism of cyanobacteria in response to light conditions is important for environmental biology because cyanobacteria are widely distributed among various ecological niches. Cyanobacteria uniquely possess circadian rhythms, with central oscillators consisting from three proteins, KaiA, KaiB, and KaiC. The two-component histidine kinase SasA/Hik8 and response regulator RpaA transduce the circadian signal from KaiABC to control gene expression. Here, we generated a strain overexpressing rpaA in a unicellular cyanobacterium Synechocystis sp. PCC 6803. The rpaA-overexpressing strain showed pleiotropic phenotypes, including slower growth, aberrant degradation of an RNA polymerase sigma factor SigE after the light-to-dark transition, and higher accumulation of sugar catabolic enzyme transcripts under dark conditions. Metabolome analysis revealed delayed glycogen degradation, decreased sugar phosphates and organic acids in the tricarboxylic acid cycle, and increased amino acids under dark conditions. The current results demonstrate that in this cyanobacterium, RpaA is a regulator of primary metabolism and involved in adaptation to changes in light conditions.

Keywords: amino acids, cyanobacteria, Synechocystis, response regulator, sugar metabolism

Introduction

Cyanobacteria are organisms performing oxygenic photosynthesis that exist in various environmental niches such as fresh water, seawater, soil, and hot springs. Studying the regulatory mechanism of cyanobacterial metabolism is important in environmental biology and biotechnology. One of the most widely studied cyanobacteria is the non-nitrogen fixing species Synechocystis sp. PCC 6803 (hereafter Synechocystis 6803). Synechocystis 6803 cells grow fast and are naturally transformable with homologous recombination (Berla et al., 2013).

Cyanobacteria have a circadian rhythm and their central oscillator consists of three proteins KaiABC, first found in the unicellular cyanobacterium Synechococcus sp. PCC 7942 (hereafter Synechococcus 7942; Ishiura et al., 1998). An important issue for study in the circadian system
is metabolic compensation, which is the persistence and entrainment of circadian rhythms in response to various nutrient conditions (Johnson and Egli, 2014). KaiC is an enzyme that phosphorylates and dephosphorylates its own residues in a strict order (Nishiwaki et al., 2007; Rust et al., 2007). ATP is a substrate of KaiC phosphorylation, and the ATP/ADP ratio is important for entrainment of the circadian clocks (Rust et al., 2011). KaiC phosphorylation is inhibited by ADP and integrates metabolic information into KaiC through the kinase-stimulation activity of KaiA (Rust et al., 2011). ATP is decreased under dark conditions and treatment with a dark pulse leads to a phase shift in the circadian clock (Rust et al., 2011). Oxidized quinones also input signals into the circadian clock in *Synechococcus* 7942 via the inhibition of KaiC phosphorylation (Kim et al., 2012). Thus, information on the availability of biochemical energy and light/dark conditions is transduced into circadian clocks. Glycogen metabolism entrains the circadian oscillator by energy and light/dark conditions is transduced into circadian clocks. Glycogen levels are decreased under light conditions and amino acid levels such as glycine and lysine are increased by *hik8* overexpression (Osanai et al., 2015). Nevertheless, in these studies, the involvement of RpaA in the regulation of primary metabolism and the effect of *rpaA* modification on metabolic alteration has remained unclear due to lack of metabolome data.

Here, we generated a *Synechocystis* 6803 strain overexpressing *rpaA*. The *rpaA*-overexpressing strain showed pleiotropic and similar phenotypes with the *hik8*-overexpressing strain. Genetic and metabolomic analyses indicate that RpaA plays pivotal roles in metabolic regulation under both light and dark conditions.

**Materials and Methods**

**Bacterial Strains and Culture Conditions**

The glucose-tolerant (GT) strain of *Synechocystis* sp. PCC 6803, isolated by Williams (1988), and the *rpaA*-overexpressing strain, designated as ROX310, were grown in modified BG-11 medium, which consisted of BG-110 liquid medium (Rippka, 1988) containing 5 mM NH$_4$Cl (buffered with 20 mM HEPES-KOH, pH 7.8). Among GT substrains, the GT-I strain was used in this study (Kanesaki et al., 2012). Liquid cultures were bubbled with 1% (v/v) CO$_2$ in air and incubated at 30°C under continuous white light (ca. 50–70 µmol photons m$^{-2}$ s$^{-1}$). Growth and cell densities were measured at OD$_{730}$ with a Hitachi U-3310 spectrophotometer (Hitachi High-Tech., Tokyo, Japan). Kanamycin (10 µg/mL) was added to ROX310 during pre-culture.

**Construction of Plasmids for *rpaA* Overexpression**

A region of the *Synechocystis* 6803 genome encoding the *rpaA* (slr0115, *rre31*) ORF was amplified by PCR using KOD Plus Neo polymerase (Toyobo, Osaka, Japan) and the specific primers 5'-GAATTATAACCATATGCCTCGAATACTGATC-3' (forward) and 5'-ATCCAAATGTGAGTTAACTCAGTTGACTACCGCC-3' (reverse). The amplified PCR fragment was inserted into the *NdeI*-*HpaI* sites of the pTKP2031V vector, using an In-Fusion HD cloning kit ( Takara Bio, Shiga, Japan). The resultant plasmid was confirmed by sequencing and transformed into GT-I as described previously (Osanai et al., 2011).

**Construction of Plasmids for Protease-Knockout Mutants**

To construct protease-knockout mutants, the coding regions of proteases were amplified by PCR with KOD Plus Neo and the following primer sets: *clpB1* (slr1641)
Iijima et al. Light regulation of primary metabolism by RpaA

**FIGURE 1** | (A) Plasmid for rpaA overexpression in *Synechocystis* 6803. The kanamycin resistance cassette was located upstream of the *psbAII* promoter. (B) Levels of rpaA transcripts in GT and ROX310 cells. Quantitative real-time PCR was performed with total RNA from cells grown under light and dark conditions. (C) Growth of GT and ROX310 cells. Left: growth of cells under photoautotrophic (PA) and photomixotrophic (PM, grown with 1 mM glucose) conditions. Right: growth of cells under light-activated heterotrophic growth conditions (LAHG, grown with 1 mM glucose under continuous dark conditions except for 15 min light per day).

5′-GGGAATTCTGCGGGATCGCAAACTA-3′ (forward) and 5′-GCGCATGCCCGCTACGGTTTCT-3′ (reverse); *clpB2* (sll0020) 5′-GGGAATTCTCGCTCTGCGATT-3′ (forward) and 5′-GCGCATGGCCAGGTCACAAACATG-3′ (reverse); *clpC* (sll0020) 5′-GGGAATTCGCTTCCTGCCCGATAG-3′ (forward) and 5′-GCGCATGCCACGTCTTCCAACAGGCGC-3′ (reverse); *clpX* (sll0535) 5′-GGGAATTCTGACACGAGCCGGTCGCAAAACTA-3′ (forward) and 5′-GCGCATGCCCGCTACGGTTTCT-3′ (reverse); *degP* (sll1204) 5′-GGGAATTCTGCGGGATCGCAAACTA-3′ (forward) and 5′-GCGCATGCCCGCTACGGTTTCT-3′ (reverse); *degQ* (sll1679) 5′-GGGAATTCTGCGGGATCGCAAACTA-3′ (forward) and 5′-GCGCATGCCCGCTACGGTTTCT-3′ (reverse); *degS* (sll1427) 5′-GGGAATTCTGCGGGATCGCAAACTA-3′ (forward) and 5′-GCGCATGCCCGCTACGGTTTCT-3′ (reverse). PCR fragments were isolated with the Wizard SV Gel and PCR Cleanup System (Promega, Madison, WI, USA) and the fragments were digested with EcoRI and *SpI*. Each of the resulting fragments was cloned into pUC119 (Clontech) digested with EcoRI and *SpI*. The chloramphenicol-resistant cassette obtained by digesting pKRP10 (Reece and Phillips, 1995) with *SmaI* or *PstI* was inserted into the *HincII* sites of *clpB2* and *clpC*, the *SmaI* sites of *clpB2* and *clpX*, and the *PstI* sites of *degP*, *degQ*, and *degS*. The resultant vectors were transformed into GT. The chloramphenicol-resistant (20 µg/mL) cells were isolated and streaked on plates several times.

**Immunoblotting**

Cells grown under light or dark conditions were collected by centrifugation (5,800 × g for 2 min), and the supernatant was removed by pipetting. The cells were frozen by liquid nitrogen. Cells were dissolved in PBS-T (137 mM NaCl, 2.7 mM KCl, 8.1 mM Na2HPO4, 1.5 mM KH2PO4, 0.1% Tween-20) and disruption by sonication and immunoblotting was performed as described previously (Osanai et al., 2014a). Antisera against SigE and GlgP (sll1356) were generated previously (Osanai et al., 2009, 2011).

**RNA Isolation and Quantitative Real-Time PCR**

RNA isolation and cDNA synthesis were performed as described previously (Osanai et al., 2014b). The cDNAs were synthesized with the SuperScript III First-Strand Synthesis System (Life Technologies Japan, Tokyo, Japan) with 2 µg of total RNA. Quantitative real-time PCR was performed with the
StepOnePlus Real-Time PCR System (Life Technologies) according to the manufacturer’s instructions, using the primers listed in Supplementary Table S2. The transcript level of *rnpB*, which encodes RNaseP subunit B, was used as an internal standard as previously described (Osanai et al., 2015).

**Glycogen Measurement**

Glycogen levels were measured at the Biotechnology Center of Akita Prefectural University (Akita, Japan), as described previously (Osanai et al., 2014b).

**LC–MS/MS Analysis**

Equal amounts of cells (10 mL of cell culture with OD<sub>730</sub> = 1.0) were harvested by rapid filtration. LC–MS/MS analysis was performed using a 100-mL aliquot of the upper phase as previously described (Osanai et al., 2014b). All metabolite analyses were performed with the cells grown without external carbon sources except CO<sub>2</sub>.

**Amino Acid Analysis by GC–MS**

Equal amounts of cells (50 mL of cell culture with OD<sub>730</sub> = 1.0) were harvested by rapid filtration. Amino acids were quantified by GC-MS as previously described (Osanai et al., 2014a).

**Organic Acid Analysis by GC–MS**

Equal amounts of cells (10 mL of cell culture with OD<sub>730</sub> = 1.0) were harvested by rapid filtration using a previously described method (Osanai et al., 2014b). GC-MS was carried out using a GCMS-QP2010 Ultra equipped with a CP-Sil 8 CB-MS capillary column (30 m × 0.25 mm × 0.25 µm; Agilent, Palo Alto, CA, USA) as previously described (Osanai et al., 2014b).

**Results**

**Slower Growth of *rpaA*-Overexpressing Strain**

We generated a strain overexpressing *rpaA* by fusing the promoter of *psbAII* (encoding Photosystem II D1 protein; Figure 1A) and the strain was named ROX310. Quantitative real-time PCR confirmed that the expression levels of *rpaA* in ROX310 were higher than in the wild-type, glucose-tolerant (GT) strain under both light and dark conditions (Figure 1B). Under both photoautotrophic and photomixotrophic conditions, the *rpaA*-overexpressing strain grew more slowly than did GT (Figure 1C). ROX310 grew similarly to GT under light-activated heterotrophic growth (LAHG) conditions until 1 day, although it lost viability under prolonged LAHG conditions (Figure 1C).
Altered Protein and Transcript Levels of SigE in ROX310

Previously, the hik8-overexpressing strain showed aberrant protein degradation of SigE, RNA polymerase sigma factors activating sugar catabolism that is essential for dark/heterotrophic conditions, after the light-to-dark transition (Osanai et al., 2015). Immunoblotting demonstrated that *rpaA* overexpression reduced the degradation of SigE proteins under dark conditions (Figure 2A). To identify the proteases of SigE, we tested seven mutants lacking orthologous proteinases related to dark conditions in *Synechococcus* 7942 (Hosokawa et al., 2011), but these knockouts did not affect SigE protein levels (Figure 2A). The level of *sigE* transcripts was higher in ROX310 than in GT under both light and dark conditions, although the levels were similarly decreased in both strains by the light-to-dark transition (Figure 2B). We then quantified the levels of sugar catabolic enzymes by immunoblotting. The protein levels of GlgP(sll1356), one of two glycogen phosphorylases involved in glycogen degradation in *Synechocystis* 6803, were not induced by the *rpaA*-overexpressing strain under dark conditions (Figure 2C).

We measured the transcript levels of genes related to sugar catabolism in ROX310 (Figure 3). The transcript levels of *pfkA(sll0765)* and *fbaII* were enhanced by *rpaA* overexpression under light conditions, while that of *pfkA(sll1196)* was repressed (Figure 3). The transcript levels of all 12 genes were decreased at 1 day after the light-to-dark transition in both GT and ROX310; however, there were higher transcript levels of these genes in ROX310 than in GT (Figure 3).

Metabolome Analysis using the Cells Grown under Light and Dark Conditions

The glycogen levels were quantified under light and dark conditions. Glycogen rapidly disappeared in GT after the light-to-dark transition (Table 1). In ROX310, glycogen decreased after

---

**FIGURE 3** | Quantitative real-time PCR analysis of transcription in GT and ROX310. Figure shows relative transcript levels of 12 genes involved in the OPP pathway (*zwf, opcA, gnd, tal*), glycogen catabolism (*glgP(sll1356), glgP(slr1367), glgX(sll0237), glgX(slr1857)*), and glycolysis (*pfkA(sll0765), pfkA(sll1196), fbAI, fbaII*). Data represent mean ± SD from three independent experiments. Transcript levels were calibrated relative to that of the corresponding transcript in GT (set at 100%). Asterisks indicate statistically significant differences between GT and ROX310 (Student’s t-test; *P* < 0.05, **P** < 0.005).
quantified by LC–MS/MS, except for those marked by #, which were quantified by GC–MS.

GT strain under light and dark conditions were cited from our previous study (Osanai et al., 2015). P, phosphate; DHAP, dihydroxyacetone phosphate. Metabolites were

the light-to-dark transition, but the glycogen degradation was slower than GT (Table 1).

LC–MS/MS analysis revealed that the levels of sugar phosphates (glucose-6-phosphate, ribose-5-phosphate, sedoheptulose-7-phosphate, fructose-6-phosphate, ribulose-5-phosphate, fructose-1,6-bisphosphate) and dihydroxyacetone phosphate were lower in ROX310 than in GT under both light and dark conditions (Table 2). Phosphoenolpyruvate levels were higher in ROX310 than in GT under light and dark conditions (Table 2). Fumarate and isocitrate levels were lower in ROX310 than in GT under light conditions (Table 2). Malate could not be detected in ROX310 under light conditions (Table 2). Organic acids in the TCA cycle were lesser in ROX310 than in GT under dark conditions (Table 2). NADP levels increased by rpaA overexpression, but other nucleotides did not (Table 2).

Amino acid analyses showed that the levels of glycine and proline were higher in ROX310 than in GT under light conditions (Figure 4). The levels of alanine, glycine, threonine, and lysine were higher in ROX310 than in GT under dark conditions (Figure 4). The level of ornithine was lower in ROX310 than in GT under dark conditions (Figure 4).

Data represent mean ± SD from four independent experiments. Metabolite levels were calibrated relative to that of the corresponding metabolite in GT under light conditions (set at 100%). Asterisks indicate statistically significant differences between GT and ROX310 (Student’s t-test; *P < 0.05, **P < 0.005). The data from the GT strain under light and dark conditions were cited from our previous study (Osanai et al., 2015). P, phosphate; DHAP, dihydroxyacetone phosphate. Metabolites were quantified by LC–MS/MS, except for those marked by #, which were quantified by GC–MS.
Alteration in Transcript Levels of Genes Encoding Circadian Clocks

Finally, expression of \(kaiABC\) genes was quantified. The transcript levels of \(kaiA, B1, C1, B2,\) and \(C2\) were doubled by \(rpaA\) overexpression under light conditions (Figure 5). The transcript levels of \(kaiB3\) and \(kaiC3\) were marginally increased in ROX310 under light conditions (Figure 5). All the transcripts of \(kaiABC\) were decreased after 1 day of dark cultivation, and the levels remained higher in ROX310 than those in GT (Figure 5).

Discussion

Here, we have performed genetic and metabolomic analyses using an \(rpaA\)-overexpressing strain and revealed that RpaA is involved in the regulation of primary metabolism in this unicellular cyanobacterium. The mechanism of circadian clocks in \(Synechocystis\) 6803, which could be different from \(Synechococcus\) 7942, has been less studied except Drs. Axmann’s and Hellingwerf’s groups (Wiegard et al., 2013; Beck et al., 2014; van Alphen and Hellingwerf, 2015), and we proceeded metabolome analyses with the circadian-related mutants of \(Synechocystis\) 6803. ChIP-Seq analysis in \(Synechococcus\) 7942, has been less studied except Drs. Axmann’s and Hellingwerf’s groups (Wiegard et al., 2013; Beck et al., 2014; van Alphen and Hellingwerf, 2015), and we proceeded metabolome analyses with the circadian-related mutants of \(Synechocystis\) 6803. ChIP-Seq analysis in \(Synechococcus\) 7942 shows that RpaA binds the promoters of \(kaiBC,\) \(sasA,\) \(rpaA,\) and genes encoding sigma factors (\(rpoD2, D5, D6\)) and sugar catabolic enzymes (\(glgP, malfQ, zwf, opcA, gap1, fbaII\)), activating their gene expression at night (Markson et al., 2013). These results are consistent with our analysis: the \(rpaA\) overexpression altered the gene expression of \(sigE,\) a sugar catabolic enzyme, and \(kaiABC\) (Figures 2, 3, and 5). SigE is a sigma factor activating glycogen catabolism, glycolysis, and the OPP pathway (Osanai et al., 2005, 2011), and its expression peaks before night (Kucho et al., 2005). Combining the results of previous and current genetic analyses, the signal transduction from the circadian clock to sugar metabolism consists of the cascade of the proteins KaiABC-Hik8-RpaA-SigE in \(Synechocystis\) sp. PCC 6803, although further promoter analysis is required. Since RpaA altered the expression of \(kaiABC\) genes (Figure 5), feedback or feedforward regulation from RpaA to the central circadian oscillator may exist to entrain the clock by metabolic information.

The \(rpaA\)-overexpressing strain of \(Synechocystis\) 6803 exhibited several phenotypes. Results from the \(rpaA\)-overexpressing strain of \(Synechocystis\) 6803 were similar to the \(rpaA\)-null mutant of \(Synechococcus\) 7942, which showed decreased glycogen catabolism (Diamond et al., 2015). The \(rpaA\) knockout mutant in \(Synechocystis\) 6803 exhibited high light sensitive phenotype (Majeed et al., 2012), which is consistent with our results that RpaA is important in light acclimation. A previous study demonstrated that introduction of RpaA(D53E; which mimics phosphorylated RpaA) restored the RpaA function, but that the introduction of RpaA(D53A; which mimics non-phosphorylated RpaA) could not (Markson et al., 2013). Therefore, the \(rpaA\) overexpression in our study may have increased non-phosphorylated RpaA in the \(Synechocystis\) 6803 cells, leading to phenotypes that were the mixture of gain-of-function and loss-of-function of RpaA. Introduction of a phospho-mimic RpaA into \(Synechocystis\) 6803 may be intriguing to distinguish these phenotypes.
Overexpression of rpaA led to phenotypes similar to those of the hik8 overexpressor (Osanai et al., 2015); that is, growth defects under light-activated heterotrophic conditions (Figure 1), aberrant degradation of SigE after the light-to-dark transition (Figure 2A), accumulated transcripts during darkness (Figure 3), decreased levels of sugar phosphates (Table 2), and increased levels of several amino acids under dark conditions (Figure 4). These similarities may be due to the overexpression of hik8 accelerated the phosphorylation of RpaA proteins. The glycogen metabolism mutant could not grow under dark/heterotrophic conditions (Osanai et al., 2005; Singh and Sherman, 2005; Tabei et al., 2007), or treatment with high salt and oxidative stress (Suzuki et al., 2010). Thus, the growth phenotypes of ROX310 under LAHG conditions may be caused by the changes in primary metabolism (Figure 1C). Genetic analyses have suggested that the mutants of Clp proteases alter circadian oscillation in Synechococcus 7942 (Holtman et al., 2005; Imai et al., 2013). Nevertheless the aberrant degradation of SigE proteins under dark conditions in the rpaA-overexpressing strain (Figure 2A), glycogen catabolism was slowed under dark conditions (Table 1). These results suggest that proteins other than SigE concertedly determine the degree of glycogen degradation in Synechocystis 6803. Several sugar catabolic regulators, including Hik31, Rre37, and AbrB are known in Synechocystis 6803 (Kahlon et al., 2006; Tabei et al., 2007; Yamauchi et al., 2011). For example, Rre37 preferentially activates the gene expression of glycogen catabolic and glycolytic enzymes such as pfkA (sll1196; Azuma et al., 2009), and thus, further study of the relationships among several sugar catabolic regulators is necessary to elucidate the regulatory mechanism of sugar catabolism in Synechocystis 6803.

Control of primary carbon metabolism by a circadian clock is an important theme in cyanobacteria (Diamond et al., 2015). Decrease in glycogen and sugar phosphates was observed during dark conditions (Tables 1 and 2), which indicates glycogen and sugar phosphates are positively correlated in this condition. On the other hand, organic acids in the TCA cycle kept higher levels under dark conditions (Table 2). Thus, organic acids in the TCA cycle were not correlated with the metabolites in glycolysis and the OPP pathway. The rpaA-overexpressing strain showed decreased levels of sugar phosphates under both light and dark conditions.
conditions (Table 2), which is consistent with the fact that RpaA is important for the expression of genes related to glycogen catabolism in unicellular cyanobacteria (Diamond et al., 2015). Our immunoblotting showed that GlgPpII1356 proteins were decreased with rpaA overexpression (Figure 2C), which may be one reason for the down-regulation of glycogen catabolism in this mutant. The metabolomic analysis also revealed that organic acids in the TCA cycle (fumarate, malate, and oxaloacetate) were lowered by rpaA overexpression (Table 2). The organic acids in the TCA cycle are an important pool of carbon sources in this cyanobacterium (Osanai et al., 2014a). Thus, the data also indicates that RpaA widely regulates primary metabolism related to the carbon sinks in this cyanobacterium. KaiC regulates the production of lysine, which has been shown to be lowered during light/dark cycles in Synechococcus 7942 (Diamond et al., 2015). The analysis showed lysine and glycine levels were up-regulated by rpaA-overexpression during the light-to-dark transition (Figure 4), demonstrating the involvement of RpaA in amino acid metabolism in response to light conditions. In summary, our metabolome analyses have revealed the RpaA-regulation in primary sugar and amino acid metabolism of Synechocystis 6803.
