Abstract

A backbone of a boolean formula $F$ is a collection $S$ of its variables for which there is a unique partial assignment $a_S$ such that $F[a_S]$ is satisfiable [MZK+99, WGS03]. This paper studies the nontransparency of backbones. We show that, under the widely believed assumption that integer factoring is hard, there exist sets of boolean formulas that have obvious, nontrivial backbones yet finding the values, $a_S$, of those backbones is intractable. We also show that, under the same assumption, there exist sets of boolean formulas that obviously have large backbones yet producing such a backbone $S$ is intractable. Further, we show that if integer factoring is not merely worst-case hard but is frequently hard, as is widely believed, then the frequency of hardness in our two results is not too much less than that frequency.

1 Introduction

An important concept in the study of the SAT problem is the notion of backbones. The term was first used by Monasson et al. [MZK+99], and the following formal definition was provided by Williams, Gomes, and Selman [WGS03].

Definition 1. Let $F$ be a boolean formula. A collection $S$ of the variables of $F$ is said to be a backbone if there is a unique partial assignment $a_S$ such that $F[a_S]$ is satisfiable.

In that definition, $a_S$ assigns a value (true or false) to each variable in $S$, and $F[a_S]$ is a shorthand meaning $F$ except with each variable in $S$ assigned the value specified for it in $a_S$. A backbone $S$ is nontrivial if $S \neq \emptyset$. The size of a backbone $S$ is the number of variables in $S$. For a backbone $S$ (for formula $F$), we say that $a_S$ is the value of the backbone $S$.

For example, every satisfiable formula has the trivial backbone $S = \emptyset$. The formula $x_1 \land \overline{x_2}$ has four backbones, $\emptyset$, $\{x_1\}$, $\{x_2\}$, and $\{x_1, x_2\}$, with respectively the values (listing values as bit-vectors giving the assignments in the lexicographical order of the names of the variables in $S$) $\epsilon$, 1, 0, and 10. The formula $x_1 \lor \overline{x_2}$ has no nontrivial backbones. (Every
formula that has a backbone will have a maximum backbone—a backbone that every other backbone is a subset of. Backbone variables have been called “frozen variables,” because each of them is the same over all satisfying assignments.)

As Williams, Gomes, and Selman [WGS03] note, “backbone variables are useful in studying the properties of the solution space of a... problem.” And that surely is so. But it is natural to hope to go beyond that and suspect that if formulas have backbones, we can use those to help SAT solvers. After all, if one is seeking to get one’s hands on a satisfying assignment of an \( F \) that has a backbone, one need but substitute in the value of the backbone to have put all its variables to bed as to one’s search, and thus to “only” have all the other variables to worry about.

The goal of the present paper is to understand, at least in a theoretical sense, the difficulty of—the potential obstacles to doing—what we just suggested. We will argue that even for cases when one can quickly (i.e., in polynomial time) recognize that a formula has at least one nontrivial backbone, it can be intractable to find one such backbone. And we will argue that even for cases when one can quickly (i.e., in polynomial time) find a large, nontrivial backbone, it can be intractable to find the value of that backbone. In particular, we will show that if integer factoring is hard, then both the just-made claims hold. Integer factoring is widely believed to be hard; indeed, if it were in polynomial time, RSA itself would fall.

In fact, integer factoring is even believed to be hard on average. And we will be inspired by that to go beyond the strength of the results mentioned above. Regarding our results mentioned above, one might worry that the “intractability” might be very infrequent, i.e., merely a rare, worst-case behavior. But we will argue that if integer factoring—or indeed any problem in \( \text{NP} \cap \text{coNP} \)—is frequently hard, then the bad behavior types we mention above happen “almost” as often: If the frequency of hardness of integer factoring is \( d(n) \) for strings up to length \( n \), then for some \( \epsilon > 0 \) the frequency of hardness of our problems is \( d(n^\epsilon) \).

None of this means that backbones are not an excellent, important concept. Rather, this is saying—proving, in fact, assuming that integer factoring is as hard as is generally believed—that although the definition of backbone is merely about a backbone existing, one needs to be aware that going from a backbone existing to finding a backbone, and going from having a backbone to knowing its value, can be computationally expensive challenges.

2 Results

Section 2.1 will formulate our results without focusing on density. Then in Section 2.2 we will discuss how the frequency of hardness of sets of the type we have discussed is related to that of the sets in \( \text{NP} \cap \text{coNP} \) having the highest frequencies of hardness.

The present section focuses only on presenting the results and what they mean. We will provide proofs in Section 3.
2.1 Basic Results

We first look at whether there can be simple sets of formulas for which one can easily compute/obtain a nontrivial backbone, yet one cannot easily find the value of that backbone. Our basic result on this is stated below as Theorem 2. In this and most of our results, we state as our hypothesis not that “integer factoring cannot be done in polynomial time,” but rather that “$P \neq NP \cap \text{coNP}$.” This in fact makes our claims stronger ones than if they had as their hypotheses “integer factoring cannot be done in polynomial time,” since it is well-known (because the decision version of integer factorization is itself in $NP \cap \text{coNP}$) that “integer factoring cannot be done in polynomial time” implies “$P \neq NP \cap \text{coNP}$.” SAT will, as usual, denote the set of satisfiable (propositional) boolean formulas. (We do not assume that SAT by definition is restricted to CNF formulas.)

**Theorem 2.** If $P \neq NP \cap \text{coNP}$, then there exists a set $A \in P$, $A \subseteq SAT$, of boolean formulas such that:

1. There is a polynomial-time computable function $f$ such that $(\forall F \in A)[f(F) \text{ outputs a nontrivial backbone of } F]$.

2. There does not exist any polynomial-time computable function $g$ such that $g(F)$ computes the value of backbone $f(F)$.

Theorem 2 remains true even if one restricts the backbones found by $f$ to be of size 1. We state that, in a slightly more general form, as follows.

**Theorem 3.** Let $k \in \{1, 2, 3, \ldots \}$. If $P \neq NP \cap \text{coNP}$, then there exists a set $A \in P$, $A \subseteq SAT$, of boolean formulas such that:

1. There is a polynomial-time computable function $f$ such that $(\forall F \in A)[f(F) \text{ outputs a size-$k$ backbone of } F]$.

2. There does not exist any polynomial-time computable function $g$ such that $g(F)$ computes the value of backbone $f(F)$.

Now let us turn to the question of whether, when it is obvious that there is at least one nontrivial backbone, it can be hard to efficiently produce a nontrivial backbone. The following theorem shows that, if integer factoring is hard, the answer is yes.

**Theorem 4.** If $P \neq NP \cap \text{coNP}$, then there exists a set $A \in P$, $A \subseteq SAT$, of boolean formulas (each having at least one variable) such that:

1. Each formula $F \in A$ has a backbone whose size is at least 49% of $F$’s total number of variables.

2. There does not exist any polynomial-time computable function $g$ such that, on each $F \in A$, $g(F)$ outputs a backbone whose size is at least 49%—or even at least 2%—of $F$’s variables.
2.2 Frequency of Hardness

A practical person might worry about results of the previous section in the following way. “Just because something is hard, doesn’t mean it is hard often. For example, regarding Theorem 4, perhaps there is a polynomial-time function $g'$ that, though it on infinitely many $F \in A$ fails to compute the value of the backbone $f(F)$, in fact for each $F \in A$ for which it fails then is correct on the next (in lexicographical order) $2^{2|F|}$ elements of $A$, where $|F|$ denotes the number of bits in the representation of $F$. In this case, the theorem is indeed true, but it is a worst-case extreme that doesn’t recognize that in reality the errors may be few and far—very, very far—between.”

In this section, we address that reasonable worry. We show that if even one problem in $\text{NP} \cap \text{coNP}$ is frequently hard, then the sets in our previous sections can be made “almost” as frequently hard, in a sense of “almost” that we will make formal and specific. Since it is generally believed—for example due to the generally believed typical-case hardness of integer factoring—that there are sets in $\text{NP} \cap \text{coNP}$ that are quite frequently hard, it follows that the $2^{2|F|}$ behavior our practical skeptic was speculating about cannot happen. Or at least, if that behavior did happen, then that would imply that every single problem in $\text{NP} \cap \text{coNP}$ has polynomial-time heuristic algorithms that make extraordinarily few errors.

We now give our frequency-of-hardness version of Theorem 2. A claim is said to hold for almost every $n$ if there exists an $n_0$ beyond which the claims always holds, i.e., the claim fails at most at a finite number of values of $n$. (In the theorems of this section, $n$’s universe is the natural numbers, $\{0, 1, 2, \ldots\}$.)

**Theorem 5.** If $h$ is any nondecreasing function and for some $B \in \text{NP} \cap \text{coNP}$ it holds that each polynomial-time algorithm, viewed as a heuristic algorithm for testing membership in $B$, for almost every $n$ (respectively, for infinitely many $n$) errs on at least $h(n)$ of the strings whose length is at most $n$, then there exist an $\epsilon > 0$ and a set $A \subseteq \text{P} \subseteq \text{SAT}$, of boolean formulas such that:

1. There is a polynomial-time computable function $f$ such that $(\forall F \in A)[f(F) \text{ outputs a nontrivial backbone of } F]$.

2. Each polynomial-time computable function $g$ will err (i.e., will fail to compute the value of backbone $f(F)$), for almost every $n$ (respectively, for infinitely many $n$), on at least $h(n')$ of the strings in $A$ of length at most $n$.

The precisely analogous result holds for Theorem 3. The analogous result also holds for Theorem 4 and we state that as the following theorem.

**Theorem 6.** If $h$ is any nondecreasing function and for some $B \in \text{NP} \cap \text{coNP}$ it holds that each polynomial-time algorithm, viewed as a heuristic algorithm for testing membership in $B$, for almost every $n$ (respectively, for infinitely many $n$) errs on at least $h(n)$ of the strings whose length is at most $n$, then there exist an $\epsilon > 0$ and a set $A \subseteq \text{P} \subseteq \text{SAT}$, of boolean formulas such that:
1. Each formula $F \in A$ has a backbone whose size is at least 49% of $F$’s total number of variables.

2. Each polynomial-time computable function $g$ will err (i.e., will fail to compute a set of size at least 2% of $F$’s variables that is a backbone of $F$), for almost every $n$ (respectively, for infinitely many $n$), on at least $h(n^\epsilon)$ of the strings in $A$ of length at most $n$.

What the above theorems say, looking at the contrapositives to the above results, is that if any of our above cases have polynomial-time heuristic algorithms that don’t make errors too frequently, then every single set in $\text{NP} \cap \text{coNP}$ (even those related to integer factoring) has polynomial-time heuristic algorithms that don’t make errors too frequently.

To make the meaning of the above results clearer, and to be completely open with our readers, it is important to have a frank discussion about the effect of the “$\epsilon$” in the above results. Let us do this in two steps. First, we give as concrete examples two central types of growth rates that fall between polynomial and exponential. And second, we discuss how innocuous or noninnocuous the “$\epsilon$” above is.

As to our examples, suppose that for some fixed $c > 0$ a particular function $h(n)$ satisfies $h(n) = 2^{\Omega((\log n)^c)}$. Note that for each fixed $\epsilon > 0$, it hold that the function $h'(n)$ defined as $h(n^\epsilon)$ itself satisfies the same bound, $h'(n) = 2^{\Omega((\log n)^c)}$. (Of course, the constant implicit in the “$\Omega$” potentially has become smaller in the latter case.) Similarly, suppose that for some fixed $c > 0$ a particular function $h(n)$ satisfies $h(n) \geq 2^{n^c}$. Then for each fixed $\epsilon > 0$ it will hold that there is a value $c' > 0$, namely, $c' = \epsilon c$, such that $h(n^\epsilon) \geq 2^{n^{c'}}$.

The above at a casual glance might suggest that the weakening of the frequency claims between the most frequently hard problems in $\text{NP} \cap \text{coNP}$ and our problems is a “mere” changing of a constant. In some sense it is, but constants that are standing on the shoulders of exponents have more of a kick than constants sitting on the ground floor. And so as a practical matter, the difference in the actual numbers when one substitutes in for them can be large. On the other hand, polynomial-time reductions sit at the heart of computer science’s formalization of its problems, and density distortions from $n$ to $n^\epsilon$ based on the stretching of reductions are simply inherent in the standard approaches of theory, since those are the distortions one gets due to polynomial-time reductions being able to stretch their inputs to length $n^{1/\epsilon}$, i.e., polynomially. For example, it is well known that if $B$ is an $\text{NP}$-complete set, then for every $\epsilon > 0$ it hold that $B$ is polynomial-time isomorphic (which is theoretical computer science’s strongest standard notion of them being “essentially the same problem”) to some set $B'$ that contains at most $2^{n^\epsilon}$ strings at each length $n$.

Simply put, the “almost” in our “almost as frequent” claims is the natural, strong claim, judged by the amounts of slack that in theoretical computer are considered innocuous. And the results do give insight into how much the density does or does not change, e.g., the first above example shows that quasi-polynomial lower bounds on error frequency remain quasi-polynomial lower bounds on error frequency. However, on the other hand, there is a weakening, and even though it is in a “constant,” that constant is in an exponent and so
can alter the numerical frequency quite a bit.\footnote{In reality, how nastily small will the “$\epsilon$” be? From looking inside the proofs of the results and thinking hard about the lengths of the formulas involved in the proofs (and resulting from the “Galil” version of Cook-Karp-Levin’s Theorem that we will be discussing in the next section), one can see that $\epsilon$’s value is primarily controlled by the running time of the NP machines for the NP sets $B$ and $\overline{B}$ from the theorems of this section. If those machines run in time around $n^k$, then $\epsilon$ will vary, viewed as a function of $k$, roughly as (some constant times) the inverse of $k$.}

3 Proofs

We now provide the proofs or proof sketches for our results. We aim more for communication than for extremely detailed rigor. However, readers not interested in proofs may wish to skip this section and the appendix.

3.1 Proofs for Section 2.1

We will prove all three of the theorems of Section 2.1 hand-in-hand, in a rather narrative fashion, as they share a framework. Each of that section’s theorems starts with the assumption that $P \neq NP \cap coNP$. So let $B$ be some set instantiating that, i.e., $B \in (NP \cap coNP) - P$. As all students learn when learning that SAT is NP-complete, we can efficiently transform the question of whether a machine accepts a particular string into a question about whether a certain boolean formula is satisfiable \cite{Coo71,Kar72,Lev75}. The original work that did that did not require (and did not need to require) that the thus-created boolean formula transparently revealed what machine and input had been the input to the transformation. But it was soon noted that one can ensure that the formula mapped to transparently reveals the machine and input that were the input to the transformation; see Galil \cite{Gal74} or our appendix.

Galil’s insight can be summarized in the following strengthened version of the standard claim regarding the so-called Cook-Karp-Levin Reduction. Let $N_1, N_2, \ldots$ be a fixed, standard enumeration of clocked, polynomial-time Turing machines, and w.l.o.g. assume that $N_i$ runs within time $n^i + i$ on inputs of length $n$, and that $N_i$ and $i$ are polynomially related in size and easily obtained from each other. There is a function $r_{Galil-Cook}$ (for conciseness, we are writing Galil-Cook rather than Galil-Cook/Karp/Levin, although this version is closer to the setting of Karp and Levin than to that of Cook, since Cook used Turing reductions rather than many-one reductions) such that

1. For each $N_i$ and $x$: $x \in L(N_i)$ if and only if $r_{Galil-Cook}(N_i, x) \in SAT$.

2. There is a polynomial $p$ such that $r_{Galil-Cook}(N_i, x)$ runs within time polynomial (in particular, with $p$ being the polynomial) in $|N_i|$ and $|x|^p + i$.

3. There is a polynomial-time function $s$ such that for each $N_i$ and $x$, $s(r_{Galil-Cook}(N_i, x))$ outputs the pair $(N_i, x)$.\footnote{In reality, how nastily small will the “$\epsilon$” be? From looking inside the proofs of the results and thinking hard about the lengths of the formulas involved in the proofs (and resulting from the “Galil” version of Cook-Karp-Levin’s Theorem that we will be discussing in the next section), one can see that $\epsilon$’s value is primarily controlled by the running time of the NP machines for the NP sets $B$ and $\overline{B}$ from the theorems of this section. If those machines run in time around $n^k$, then $\epsilon$ will vary, viewed as a function of $k$, roughly as (some constant times) the inverse of $k$.}
We will be using two separate applications of the \( r \) function in our construction. But we need those two applications to be variable-disjoint. We will need this as otherwise we’d have interference with some of our claims about sizes of backbones and which variables are fixed and how many variables we have. These are requirements not present in any previous work that used the \( r \) function of Galil-Cook. We also will want to be able to have some literal names (in particular, “\( z \)”-using literal names of the form \( z_\ell, z'_\ell, z_{\ell}, \) or \( \overline{z}_\ell \) for all \( \ell \)) available to us that we know are not part of the output of any application of the Galil-Cook \( r \) function; we need them as our construction involves not just two applications of the \( r \) function but also some additional variables. We can accomplish all the special requirements just mentioned as follows. We will, w.l.o.g., assume that in the output of the Galil-Cook function \( r_{\text{Galil-Cook}}(N_i, x) \), every variable is of the form \( x_j \) (the \( x \) there is not a generic example of a letter, but really means the letter “\( x \)” just a “\( z \)” earlier really means the letter “\( z \)”)), where \( j \) itself, when viewed as a pair of integers via the standard fixed correspondence between \( \mathbb{Z}^+ \) and \( \mathbb{Z}^+ \times \mathbb{Z}^+ \), has \( N_i \) as its first component or actually, to be completely precise, the natural number corresponding to \( N_i \) in the standard fixed correspondence between positive integers and strings. Though not all implementations of the Galil-Cook \( r \) function need have this property (and in fact, none has previously satisfied it as far as we know), we claim that one can implement a legal Galil-Cook \( r \) function in such a way that it has this property yet still has the property that this \( r \) function will have a polynomial-time inversion function \( s \) satisfying the behavior for \( s \) mentioned above. (For those wanting more information on how such a function \( r_{\text{Galil-Cook}}(N_i, x) \) can be implemented that has all the properties claimed above, we have included as a technical appendix, namely as Appendix \[A\] a construction we have built that accomplishes this.)

We now can specify the sets \( A \) needed by the theorems of Section 2.1. Recall we have (thanks to the assumptions of the theorems) fixed a set \( B \in (\text{NP} \cap \text{coNP}) - \text{P} \). \( B \in \text{NP} \) so let \( i \) be a positive integer such that \( N_i \) is a machine from the abovementioned standard enumeration such that \( L(N_i) = B \). \( \overline{B} \in \text{NP} \) so let \( j \) be a positive integer such that \( N_j \) is a machine from the abovementioned standard enumeration, such that \( L(N_j) = \overline{B} \). Fix any positive integer \( k \). Then for the case of that fixed value \( k \), the set \( A \) of Theorem 3 is as follows:

\[
A_{3,k} = \{ (z_1 \land z_2 \land \cdots \land z_k \land (r_{\text{Galil-Cook}}(N_i, x))) \lor (\overline{z}_1 \land \overline{z}_2 \land \cdots \land \overline{z}_k \land (r_{\text{Galil-Cook}}(N_j, x))) \mid x \in \Sigma^* \}.
\]

One must keep in mind in what follows that, as per the previous paragraph, \( r_{\text{Galil-Cook}} \) never outputs literals with names involving subscripted \( z \)’s or \( \overline{z} \)’s and the outputs of \( r_{\text{Galil-Cook}}(N_i, x) \) and \( r_{\text{Galil-Cook}}(N_j, x) \) share no variable names (since \( i \neq j \)).

Let us argue that \( A_{3,k} \) indeed satisfies the requirements of the \( A \) for the “\( k \)” case of Theorem 3.

\( A \in \text{P} \): Given a string \( y \) whose membership in \( A \) we are testing, we make sure \( y \) syntactically matches the form of the elements of \( A \) (i.e., elements of \( A_{3,k} \)). If it does, we then check that its \( k \) matches our \( k \), and we use \( s \) to get decoded pairs \( (i', x') \) and \( (j'', x'') \) from the places in our parsing of \( y \) where we have formulas—call them \( F_{\text{left}} \) and \( F_{\text{right}} \)—that we are hoping are the outputs of the \( r \) function. That is, if our input parses as \( (z_1 \land z_2 \land \cdots \land z_k \land (F_{\text{left}})) \lor (\overline{z}_1 \land \overline{z}_2 \land \cdots \land \overline{z}_k \land (F_{\text{right}})) \), then if \( s(F_{\text{left}}) \) gives \( (N_i, x') \) our decoded pair is \( (i', x') \), and \( F_{\text{right}} \) is handled analogously. We also check to make sure that
If anything mentioned so far fails, then \( y \notin A \). Otherwise, we check to make sure that \( r_{\text{Galil-Cook}}(N_i, x') = F_{\text{left}} \) and \( r_{\text{Galil-Cook}}(N_j, x') = F_{\text{left}} \), and reject if either equality fails to hold. (Those checks are not superfluous. \( s \) by definition has to correctly invert on strings that are the true outputs of \( r_{\text{Galil-Cook}} \), but we did not assume that \( s \) might not output sneaky garbage when given other input values, and since \( F_{\text{left}} \) and \( F_{\text{right}} \) are coming from our arbitrary input \( y \), they could be anything. However, the check we just made defangs the danger just mentioned.) If we have reached this point, we indeed have determined that \( y \notin A \), and for each \( y \in A \) we will successfully reach this point.

**A \subseteq \text{SAT}**: For each \( x \), either \( x \in B \) or \( x \notin B \). In the former case (\( x \in B \)), \( r_{\text{Galil-Cook}}(N_i, x) \in \text{SAT} \) and so the left disjunct of \((z_1 \land z_2 \land \cdots \land z_k \land (r_{\text{Galil-Cook}}(N_i, x))) \lor (\overline{z_1} \land \overline{z_2} \land \cdots \land \overline{z_k} \land (r_{\text{Galil-Cook}}(N_j, x)))\) can be made true using that satisfying assignment and setting each \( z_\ell \) to true. On the other hand, if \( x \notin B \), then \( r_{\text{Galil-Cook}}(N_j, x) \in \text{SAT} \) and so the whole formula can be made true using that satisfying assignment and setting each \( z_\ell \) to false.

There is a polynomial-time computable function \( f \) such that \((\forall F \in A)[f(F)] \) outputs a nontrivial backbone of \( F \): On input \( F \in A \), \( f \) will simply output \( \{z_1, z_2, \ldots, z_k\} \), which is a nontrivial backbone of \( F \). Why is it a nontrivial backbone? If the \( x \) embedded in \( F \) satisfies \( x \in B \), then not only does \( r_{\text{Galil-Cook}}(N_i, x) \in \text{SAT} \) hold, but also \( r_{\text{Galil-Cook}}(N_j, x) \notin \text{SAT} \) must hold (since otherwise we would have \( x \notin B \land x \in B \), an impossibility). So if the \( x \) embedded in \( F \) satisfies \( x \in B \), then there are satisfying assignments of \((z_1 \land z_2 \land \cdots \land z_k \land (r_{\text{Galil-Cook}}(N_i, x))) \lor (\overline{z_1} \land \overline{z_2} \land \cdots \land \overline{z_k} \land (r_{\text{Galil-Cook}}(N_j, x)))\), and every one of them has each \( z_\ell \) set to true. Similarly, if the \( x \) embedded in \( F \) satisfies \( x \notin B \), then our long formula has satisfying assignments, and every one of them has each \( z_\ell \) set to false. Thus \( \{z_1, z_2, \ldots, z_k\} \) indeed is a size-\( k \) backbone.

There does not exist any polynomial-time computable function \( g \) such that \( g(F) \) computes the value of backbone \( f(F) \): Suppose by way of contradiction that such a polynomial-time computable function \( g \) does exist. Then we would have that \( B \in \text{P} \), by the following algorithm. Let \( f \) be the function constructed in the previous paragraph, i.e., the one that outputs \( \{z_1, z_2, \ldots, z_k\} \) when \( F \in A \). Given \( x \), in polynomial time—\( g \) and \( f \) are polynomial-time computable, and although \( r \) in general is not since its running time’s polynomial degree varies with its first argument and so is not uniformly polynomial, \( r \) here is used only for the first-component values \( N_i \) and \( N_j \) and under that restriction it indeed is polynomial-time computable—compute \( g(f((z_1 \land z_2 \land \cdots \land z_k \land (r_{\text{Galil-Cook}}(N_i, x))) \lor (\overline{z_1} \land \overline{z_2} \land \cdots \land \overline{z_k} \land (r_{\text{Galil-Cook}}(N_j, x)))))), \) which must either tell us that the \( z_\ell \)s are true in all satisfying assignments, which tells us that it is the left disjunct that is satisfiable and thus \( x \in B \), or it will tell us that the \( z_\ell \)s are false in all satisfying assignments, from which we similarly can correctly conclude that \( x \notin B \). So \( B \in \text{P} \), yet we chose \( B \) so as to satisfy \( B \in (NP \cap \text{coNP}) - \text{P} \). Thus our assumption that such a \( g \) exists is contradicted.

That ends our proof of Theorem 4—and so implicitly also of Theorem 2 since Theorem 2 follows immediately from Theorem 8.
one that proves Theorem 4. Recall that for the “k” case of Theorem 3, our set $A$ was 
$\{ (z_1 \land z_2 \land \cdots \land z_k \land (r_{Galil-Cook}(N_i, x)) ) \land (z_{k+1} \land z_{k+2} \land \cdots \land z_m \land (r_{Galil-Cook}(N_j, x))) \mid x \in \Sigma \}$. 

For Theorem 3, let us use almost the same set. Except we will make two types of changes. First, in the above, replace the two occurrences of $k$ each with the smallest positive integer $m'$ satisfying 
\[ \text{numvars}(r_{Galil-Cook}(N_i, x)) + \text{numvars}(r_{Galil-Cook}(N_j, x)) + 2m' \geq \frac{49}{100}, \]
where \text{numvars} counts the number of variables in a formula, e.g., \text{numvars}(\overline{x_1} \land \overline{x_2} \land \overline{x_3}) = 2, due to the variables $x_1$ and $x_2$. Let $m$ henceforth denote that value, i.e., the smallest (positive integer) $m'$ that satisfies the above equation. Second, in the right disjunct, change each $\overline{z_i}$ to $z_i$. 

Note that if $x \in B$, then $\{z_1, z_2, \ldots, z_m\}$ is a backbone whose value is the assignment of true to each variable, and that contains at least 49% of the variables in the formula that $x$ put into $A$. Similarly, if $x \notin B$, then $\{z'_1, z'_2, \ldots, z'_m\}$ is a backbone whose value is the assignment of false to each variable, and that contains at least 49% of the variables in the formula that $x$ put into $A$. It also is straightforward to see that our thus-created set $A$ belong to $P$ and satisfies $A \subseteq \text{SAT}$. 

So the only condition of Theorem 4 that we still need to show holds is the claim that, for the just-described $A$, there does not exist any polynomial-time computable function $g$ such that, on each $F \in A$, $g(F)$ outputs a backbone whose size is at least 2% of $F$’s variables. Suppose by way of contradiction that such a function $g$ does exist. We claim that would yield a polynomial-time algorithm for $B$, contradicting the assumption that $B \notin P$. Let us give such a polynomial-time algorithm. To test whether $x \in B$, in polynomial time we create the formula in $A$ that is put there by $x$, and we run our postulated polynomial-time $g$ on that formula, and thus we get a backbone, call it $S$, that contains at least 2% of $F$’s variables. Note that we ourselves do not get to choose which large backbone $g$ outputs, so we must be careful as to what we assume about the output backbone. We in particular certainly cannot assume that $g$ happens to always output either $\{z_1, z_2, \ldots, z_m\}$ or $\{z'_1, z'_2, \ldots, z'_m\}$. But we don’t need it to. Note that the two backbones just mentioned are variable-disjoint, and each contains 49% of $F$’s variables. 

Now, there are two cases. One case is that $S$ contains at least one variable of the form $z_{\ell}$ or $z'_{\ell}$. In that case we are done. If it contains at least one variable of the form $z_{\ell}$ then $x \in B$. Why? If $x \in B$, then the left-hand disjunct of the formula $x$ puts into $A$ is satisfiable and the right-hand disjunct is not. From the form of the formula, it is clear that each $z_{\ell}$ is always true in each satisfying assignment in this case, yet that for each $z'_{\ell}$ there are satisfying assignments where $z'_{\ell}$ is true and there are satisfying assignments where $z'_{\ell}$ is false. So if $x \in B$, no $z'_{\ell}$ can belong to any backbone.

By analogous reasoning, if $S$ contains at least one variable of the form $z'_{\ell}$ then $x \notin B$. (It follows from this and the above that $S$ cannot possibly contain at least one variable that is a subscripted $z$ and at least one variable that is a subscripted $z'$, since then $x$ would have to simultaneously belong and not belong to $B$.)

The final case to consider is the one in which $S$ does not contain at least one variable of the form $z_{\ell}$ or $z'_{\ell}$. We argue that this case cannot happen. If this were to happen, then...
every variable of \( F \) other than the variables \( \{z_1, z_2, \cdots, z_m, z'_1, z'_2, \cdots, z'_m\} \) must be part of the backbone, since \( S \) must involve 2\% of the variables and \( \{z_1, z_2, \cdots, z_m, z'_1, z'_2, \cdots, z'_m\} \) comprise 49\% of the variables. But that is impossible. We know that the variables used in \( r_{\text{Galil-Cook}}(N_i, x) \) and \( r_{\text{Galil-Cook}}(N_j, x) \) are disjoint. So the variables in the one of those two that is not the one that is satisfiable can and do take on any value in some satisfying assignment, and so cannot be part of any backbone. (The only remaining worry is the case where one of \( r_{\text{Galil-Cook}}(N_i, x) \) or \( r_{\text{Galil-Cook}}(N_j, x) \) contains no variables. However, the empty formula is by convention considered illegal, in cases such as here where the formulas are not considered to be trapped into DNF or CNF. There is a special convention regarding empty DNF and CNF formulas, but that is not relevant here.)

We have thus concluded the proof of Theorem 4.

3.2 Proof Sketches for Section 2.2

We will treat this section briefly and informally, as we will argue that its claims can be seen as following from the previous section’s proofs.

The crucial thing to note is that the mapping from strings \( x \) (as to whether they belong to \( B \)) into the string that \( x \) puts into \( A \) is (a) polynomial-time computable (and so the one string that \( x \) puts into \( A \) is at most polynomially longer than \( x \)), and (b) one-to-one.

So, any collection of \( m \) instances up to a given length \( n \) that fool a particular polynomial-time algorithm for \( B \) are associated with at least \( m \) distinct instances in \( A \) all of length at most \( n^q \) (where the polynomial bound on the length of the formula that \( x \) puts into \( A \) is that it is of length at most \( n^{1/2} \)). So if one had an algorithm for the “\( A \)” set such that the algorithm had at most \( m' \) errors on the strings up to length \( n^q \), it would certainly imply an algorithm for \( B \) that up to length \( n^{1/q} \) made at most \( m' \) errors. Namely, one’s heuristic of that form for \( B \) would be to take \( x \), map it to the string it put into \( A \), and then run the heuristic for \( A \) on that string.

The above discussion establishes what the results in Section 2.2 are asserting.

4 Related Work

Our results can be viewed as part of a line of work that is so underpopulated as to barely merit being called a line of work, at least regarding its connections to AI. The true inspiration for this work was a paper of Alan Demers and Allan Borodin [BD76] from the 1970s that never appeared in any form other than as a technical report. Though quite technical, that paper in effect showed sufficient conditions for creating simple sets of satisfiable formulas such that it was unclear why they were satisfiable.

2 We have for simplicity in this brief analysis left out any lower-order terms and the leading-term constant, but that is legal except at \( n \in \{0, 1\} \)—since starting with \( n = 2 \) we can boost \( q \) if needed—and no finite set of values, such as \( \{0, 1\} \) can cause problems to our theorem, as it is about the “infinitely-often” and “almost-everywhere” cases. However, such boosting does potentially interfere with the inverse-of-\( k \) relation mentioned in Footnote 3 and so if we wanted to maintain that, we would in this argument instead use a lowest-degree-possible monotonic polynomial bounding the growth rate.
Even in the theoretical computer science world, where Borodin and Demers’s work is set, the work has been very rarely used. In particular, it has been used to get characterizations regarding unambiguous computation [HHSS], and Rothe and his collaborators have used it in various contexts to study the complexity of certificates [HRW97, Rot99], see also Fenner et al. [FFNR03] and Valiant [Val76].

There has been just one paper that previously has sought to bring the focus of this line to a topic of interest in AI. Although it appeared in a theoretical computer science venue, the work of Hemaspaandra, Hemaspaandra, and Menton [HHM13] shows that some problems from computational social choice theory, a subarea of multiagent systems, have the property that if \( P \neq NP \cap \text{coNP} \) then their search versions are not polynomial-time Turing reducible to their decision problems—a rare behavior among the most familiar seemingly hard sets in computer science, since so-called self-reducibility [MP79] is known to preclude that possibility for most standard NP-complete problems. The key issue that 2013 paper left open is whether the type of techniques it used, descended from Borodin and Demers [BD76], might be relevant anywhere else in AI, or whether its results were a one-shot oddity. The present paper in effect is arguing that the former is the case. Backbones are a topic important in AI and relevant to SAT solvers, and this paper shows that the inspiration of the line of work initiated by Borodin and Demers [BD76] can be used to establish the opacity of backbones.

It is important to acknowledge that our proofs regarding Section 2.1 are drawing on elements of the insights of Borodin and Demers [BD76], although in ways unanticipated by that paper. And the addition of density transfer arguments to the world of Borodin-Demers arguments is due to Hemaspaandra, Hemaspaandra, and Menton [HHM13], and we are benefiting from that argument.

5 Conclusions

We argued, under assumptions widely believed to be true such as the hardness of integer factoring, that knowing a large backbone exists doesn’t mean one can efficiently find a large backbone, and finding a nontrivial backbone doesn’t mean one can efficiently find its value. Further, we showed that one can ensure that these effects are not very infrequent, but rather that they can be made to happen with “almost” the same density of occurrence as the error rates of the most densely hard sets in \( NP \cap \text{coNP} \).

Most of our results relied on the assumption that \( P \neq NP \cap \text{coNP} \), which as noted above is likely true, since if it is false then integer factoring is in \( P \) and the RSA encryption scheme falls. It would be interesting, however, to see whether one can get any (likely weaker) backbone-opacity results under the weaker assumption that \( P \neq NP \). We in fact have done so, but we consider those results unsatisfying, and they in effect rely on a particular feature of the Williams, Gomes, and Selman [WGS03] definition of backbones, namely, that unsatisfiable formulas have no backbones. That feature has no effect on the results of this paper, since in all our theorems we produced sets \( A \) whose elements all are satisfiable formulas.

A Appendix: Construction of a Galil-Cook $r$ Function with the Properties Claimed in Section 2.1

For those who wish to be assured that a Galil-Cook “$r$” function can be implemented so as to have all the properties we have “without loss of generality” assumed in Section 2.1 we here provide such an implementation.

Let $N_1, N_2, \ldots$ be as in Section 2.1. That is, it is a fixed, standard enumeration of clocked, polynomial-time Turing machines, such that each $N_i$ runs within time $n^i + i$ on inputs of length $n$, and $N_i$ and $i$ are polynomially related in size and easily obtained from each other. Fix any function $r$ that implements the Cook-Karp-Levin reduction. That is, $r$ is such that

1. for each $N_i$ and $x$: $x \in L(N_i)$ if and only if $r(N_i, x) \in SAT$.
2. there is a polynomial $p$ such that $r(N_i, x)$ runs within time polynomial (in particular, with $p$ being the polynomial) in $|N_i|$ and $|x|^i + i$.

It is very well known that such functions exist. Their existence—the Cook-Karp-Levin reduction—is proven in almost every textbook that covers NP-completeness (see, e.g., Hopcroft and Ullman [HU79]), and is the key moment that brings the theory of NP-completeness to life, by transferring the domain from machines to a concrete problem that itself can be used to show that other concrete NP problems are themselves NP-complete.

Note that the function $r$ that we have thus fixed is not assumed to necessarily have an “inversion” function $s$, and is not assumed to necessarily avoid using literals involving the letter “z”, and is is not assumed to necessarily have the property that two applications of the $r$ function are guaranteed to be variable-disjoint if they regard different machines (i.e., are not both about $N_i$ for the same value $i$).

We now show how to use the above fixed function $r$ as a building block to build our function $r_{Galil-Cook}$, which will have all the properties just mentioned, yet will retain the time and reduction-to-SAT properties mentioned above regarding $r$. $r_{Galil-Cook}$, when its first argument is $N_i$ and its second argument is $x$, does the following. It simulates the run of $r$ when its first argument is $N_i$ and its second argument is $x$, and so computes the formula $r_{Galil-Cook}(N_i, x)$, which we will henceforth denote by $F$ for conciseness of notation. It then
counts the number of variables occurring in that formula $F$; let us denote that number by $p$. (So for example if the formula $F$ is $z_1 \land \overline{z_1} \land \overline{w}$, then $p = 2$, as there are two variables, $z_1$ and $w$.) Now, let $F'$ denote $F$, except each variable $a$ in $F$ will be replaced in $F'$ by the variable $x_{\langle N_i, q \rangle}$, where $q$ is the location of $a$ in lexicographic order within the variables of $F$. ($\langle \cdot, \cdot \rangle$ is any standard, nice, easily computable, easily invertible pairing function.) If we view $w$ as coming lexicographically before $z_1$, then in our example, $F'$ would be $x_{\langle N_i, 2 \rangle} \land x_{\langle N_i, 2 \rangle} \land x_{\langle N_i, 1 \rangle}$. Despite the pairings used, this increases the length of $F$ by at most a multiplicative factor of the number of bits of $N_i$. (Since each of our uses of $r_{\text{Galil-Cook}}$ in Section 2.1 only used the function on some two hypothetical, fixed machines, the time and length-of-output effect of this variable-renaming is at most a multiplicative constant (that depends on the two machines), and so is negligible in standard complexity-analysis terms). But although using the same trick to encode $x$ into the output by pairing it too into the variable names would be valid, it would increase the formula size by a multiplicative factor of $|x|$, which is not negligible. So we take a different approach, which instead increases the formula size just by an additive factor of $O(|x|)$. $r_{\text{Galil-Cook}}(N_i, x)$ will output $(F') \land (c_0 \lor c_1 \lor c_0 \lor \cdots \lor c_{b_i})$, where in the above $b_i$ denotes the value of the $i$th bit of $x$ and each $c_0$ above means to write $x_{\langle N_i, p+1 \rangle}$ and each $c_1$ above means to write $x_{\langle N_i, p+1 \rangle}$.

So, in our running example, if the value of $x$ was 101, $r_{\text{Galil-Cook}}(N_i, x)$ would be $(x_{\langle N_i, 2 \rangle} \land x_{\langle N_i, 1 \rangle}) \land (x_{\langle N_i, 3 \rangle} \lor x_{\langle N_i, 3 \rangle} \lor x_{\langle N_i, 3 \rangle} \lor x_{\langle N_i, 3 \rangle})$.

It is not hard to see that the $r_{\text{Galil-Cook}}$ we have constructed has all the promised properties. It has the correct running time, it validly reduces from whether $N_i$ accepts $x$ to the issue of whether $r_{\text{Galil-Cook}}(N_i, x)$ is in SAT, it never outputs any literal involving the letter $z$, all its literals in fact are tagged by the $N_i$ in use and so two applications created with regard to different machines (e.g., $N_4$ and $N_7$) are guaranteed to have variable-disjoint outputs, and it even is such that the desired $s$ function exists. Our $s$ function will take an input, parse it to get $(A) \land (B)$, will decode $N_i$ from the variables names in $A$ and will decode $x$ from the fact that it is basically written out by the bits encoded by all but the first two disjuncts of $B$, and then will output the pair $(N_i, x)$. If anything goes wrong in that process, as to unexpected syntax or so on, then what we were given is not an actual output of some run of $r_{\text{Galil-Cook}}$ on a legal input, and we can output any junk pair that we like, without violating our promise as to the behavior of $s$. (Some inputs that are not valid outputs of $r_{\text{Galil-Cook}}$ will not trigger the above “if anything goes wrong,” since we did not here take the $(N_i, x)$ we are about to output and compute $r_{\text{Galil-Cook}}(N_i, x)$ to see whether the output of that matches our input. But we do not need to. The needed behavior here is that all valid inputs have the right output, and we have achieved that.)
