Abstract

We perform a lattice study of heavy baryons, containing one ($\Lambda_b$) or two $b$-quarks ($\Xi_b$). Using the quenched approximation we obtain for the mass of $\Lambda_b$

$$M_{\Lambda_b} = 5.728 \pm 0.144 \pm 0.018\text{GeV}.$$  

The mass splitting between the $\Lambda_b$ and the B-meson is found to increase by about 20\% if the light quark mass is varied from the chiral limit to the strange quark mass.

1 Introduction

Considerable progress has been achieved in the computation of low lying hadronic states from lattice QCD (LQCD). It turned out that quenched LQCD reproduces the hadron spectrum in the light quark sector surprisingly well, once finite volume corrections are carefully taken into account [1]. This holds in particular for the ratio $m_N/m_\rho$, which has been a notorious problem for LQCD over quite some years.

Beauty physics is attracting much attention because the origin of CP violation in the B-system is still an open question. The investigation of such a system is a great challenge to LQCD. Considerable progress has been made in the lattice studies of heavy-light mesons like D- and B-mesons [2].

Heavy-light systems from the baryonic sector so far have been studied with lattice methods exploratively in the limit of infinite heavy quark mass [3, 4].

Throughout the current study the mass of the heavy quark has been kept finite. We will present results for the mass of $\Lambda_b$, a baryon composed of a $b$-quark and two light quarks, as well as for the mass of $\Xi_b$, a baryon composed of two $b$-quarks and one light quark.

As in the case of heavy-light mesons, the most dangerous source of systematic error stems from the fact that one is forced — in order to enter the region of heavy quark masses — to actually push the heavy mass close to the very limit of current lattice resolutions. We will attempt, however, to keep control on these effects of a finite lattice spacing $a$ by a variety of precautions:

1. We avoid to compute the masses of the $\Lambda_b$ and the $\Xi_b$ directly, but rather calculate the mass splittings $\Delta\Lambda = M_{\Lambda_b} - M_B$ and $\Delta\Xi = M_{\Xi_b} - 2M_B$, with respect to the B-meson mass $M_B$. These splittings do not depend on the heavy quark mass in the infinite mass limit and are therefore less prone to contamination by finite $a$ effects in the $b$ and $c$ quark mass regions.

2. We monitor the dependence of the splittings on the lattice spacing for our three $\beta$ values, $\beta = 5.74, 6.0, 6.26$. This enables us (a) to check the assumption of weak $a$ dependence and (b) to perform an $a \to 0$ extrapolation.

3. We will not calculate directly the mass splittings too close to the $b$ quark mass. Instead we stop the calculation at approximately twice the charm quark mass and then extrapolate our data to the $b$ mass.

Moreover, we investigate finite size effects at $\beta = 5.74$, on three lattices of spatial volumes $8^3, 10^3$ and $12^3$, in lattice units. Our lattice parameters
are detailed in table 1. To obtain a good signal for the ground state, we use smeared gauge invariant interpolating quark fields [5], defined for the standard Wilson action.

| $N_S$ | $N_T$ | no. configs. | $\beta$ | $a\,m_\rho$ |
|-------|-------|-------------|--------|-------------|
| 8     | 24    | 175         | 5.74   | 0.542 ± 0.014 |

Table 1: Lattice parameters: space and time extents $N_S$ and $N_T$, number of configurations, $\beta$ and the $\rho$-mass in lattice units.

2 Smearing Techniques and Volume Effects

For the reasons given above, we will compute the baryonic masses with reference to the mass of the B-meson, by proper combinations that would eliminate the $b$-quark mass in the heavy quark limit. So we consider the splittings $\Delta \Lambda = M_{\Lambda_b} - M_B$ and $\Delta \Xi = M_{\Xi_b} - 2M_B$, respectively, in the single and double beauty sectors. In the first case, we need to compute the correlators, for the heavy-light pseudoscalar meson,

$$C_P(t) = \sum_{\vec{x}} \langle \left( \bar{Q}(x)\gamma^5 q^J(x) \right) \left( \bar{q}^J(0)\gamma^5 Q(0) \right) \rangle,$$

and for the $\Lambda$ baryon

$$C_\Lambda(t) = \sum_{\vec{x}} \langle \left( \epsilon^{abc} Q_a(x) \left( q_b^J(x) C \gamma_5 q_c^J(x) \right) \right) \right\rangle \left( \epsilon^{abc} Q_a(0) \left( q_b^J(0) C \gamma_5 q_c^J(0) \right) \right),$$

where $Q(x) = Q(\vec{x}, t)$ is the heavy quark field, and $q^J(x) = q^J(\vec{x}, t)$ is the light one, to which smearing of type $J$ [5] has been applied. $C$ is the charge

\[\text{2The correlator for the } \Xi \text{ is obtained from the one for the } \Lambda \text{, by replacing the light quark } q_b^J \text{ by a heavy one } Q_b.\]
conjugation operator given by $C = i\gamma^4\gamma^2$.

Given the lattice results for these correlators, we perform a direct fit to their ratio

$$R_\Lambda(t) = \frac{C_\Lambda(t)}{C_P(t)} \to Ae^{-\Delta_\Lambda t}$$

in the large $t$ limit.

It is by now well known that smearing [3, 7, 8] is crucial to obtain a decent overlap of the operators with the ground state. In this work, we make use of the experience acquired previously while computing properties of the heavy-light pseudoscalar states [3], where we found gauge-invariant ‘Gaussian type’ wave functions (of r.m.s radius 0.3 fm) to provide sufficient overlap. The smearing was applied to the light quark source in the mesonic case. In this study, we are using precisely this procedure for the heavy-light baryons as well, without any further optimization.

In order to establish ground state dominance we look for a plateau in the local mass of the ratio $R_\Lambda$. In fig. 1a we show as an example the local mass of $R_\Lambda$, for the two largest lattices: the solid line shows the fitted value for the plateau. Fig. 1b shows the corresponding local mass for the ratio $R_\Xi(t) = C_\Xi(t)/C_P^2(t)$ used to determine $\Delta_\Xi$. These figures show the quality of the plateaus for representative $\kappa$ values. Worse quality is found only in a few cases, and it resulted in larger statistical errors; for instance the two largest $\kappa$ values at $\beta = 5.74$ given in table 3.

The pseudoscalar mass was extensively studied in ref. [9] and the values have been taken from there.

For checking the finite volume effects, we computed $\Delta_\Lambda$ on three lattices with $N_T = 24$, $\beta = 5.74$ and sizes $N_S = 8$, 10, 12, for $\kappa_l = 0.156$, and $\kappa_h = 0.125, 0.140, 0.150$. We compare the results for the splitting in table 4. The values exhibit deviations of at most 4%. In fig. 2 we plot the dimensionless ratio $\Delta_\Lambda/m_\rho$ as a function of $L$, the lattice size in units of $m_\rho$; as can be seen, for these values of $\kappa_h$, the finite size effects of this ratio are smaller than our statistical errors.

In the following, we will fix the volume to about 1 fm (which corresponds to $N_S \simeq 8, 12$ and 18 for $\beta = 5.74, 6.0$ and 6.26 respectively) and carry out a detailed study of the extrapolation to the continuum limit. As a tribute to possible finite size effects we will add the above maximal variation of 4% as an uncertainty to all results.
The results for $\Delta^{}_{\Lambda}$ at the three $\beta$ values 5.74, 6.00 and 6.26 at fixed volume are listed in table 3, all in lattice units. The extrapolations to $u$ and $s$-type light quarks, — for given heavy quark $\kappa_h$ — are performed as described in [3].

Since we are evaluating masses, it is natural to use $m^{}_{\rho}$ to set the lattice scale. The values of $m^{}_{\rho}$ for the various lattices have been listed in table 1; the experimental value used is: $m^{}_{\rho} = 768$ MeV.

In fig. 3a we plot $\Delta^{}_{\Lambda}$ in GeV extrapolated to the chiral limit as a function of $1/M^{}_{P}$ in GeV$^{-1}$. Within the statistical precision achieved in this computation, the points show no dependence on $a$, although $a$ is varied by about a factor two (cf. Table 1).

In the continuum, the $1/M^{}_{P}$ expansion for $\Delta^{}_{\Lambda}$ gives

$$\Delta^{}_{\Lambda}^{}(M^{}_{P}) = c_0 + \frac{c_1}{M^{}_{P}} + O(M^{}_{P}^{-2}).$$

(4)

Assuming no dependence on the lattice spacing, this form can be fitted directly to the points in fig. 3a yielding $\Delta^{}_{\Lambda_b} = 431(28)$ MeV at the mass of the B-meson. This result is included in the figure as the inverted triangle. The error bar of this point does not account for the fact that the simulation results exclude an $a$-dependence only within their precision.

A realistic error that includes the uncertainty of extrapolating the lattice data to the continuum is obtained by allowing for the leading $a$-dependence at each value of $M^{}_{P}$ [4]: We start out from a selected value of $M^{}_{P}$ (in physical units) and interpolate the lattice results from each (fixed) $\beta$-value to the value of $M^{}_{P}$. This enables us to compare $\Delta^{}_{\Lambda}$ at different values of $a$. A subsequent

Table 3: The mass splittings \( \Delta_\Lambda \) and \( \Delta_\Xi \) at the chiral limit and at the strange quark mass in lattice units for \( \beta = 5.74, 6.00, 6.26 \). The last column gives the ratio \( \Delta_\Lambda(m_s)/\Delta_\Lambda(m_u) \) for the same \( \beta \) values.
linear extrapolation in $a$ will then yield the continuum estimate for $\Delta_\Lambda$, at the chosen physical value of $M_P$.

Reiteration of the procedure on a set of masses $M_P$ determines the numerical dependence of $\Delta_\Lambda^{\text{cont.}}$ on $M_P$. In order to remain in compliance with the assumption of linearity in $a$, we used only a subset of the data listed in table 3, by excluding the data for the two heaviest masses at any value of $\beta$.

A final fit of the continuum limit values $\Delta_\Lambda^{\text{cont.}}$ to eq. (4) yields

$$\Delta_\Lambda = 458 \pm 144 \pm 18 \text{ MeV}. \quad (5)$$

Here the first error is purely statistical and stems from a full jacknife analysis of our data. The second error represents the 4% uncertainty due to finite volume effects. Together with the known experimental value $M_B = 5.27$ GeV, we obtain an estimate for the mass of $\Lambda_b$:

$$M_{\Lambda_b} = 5.728 \pm 0.144 \pm 0.018 \text{ GeV}. \quad (6)$$

We note in passing, that the parameter $c_0$ is in agreement with the estimates obtained directly in the static approximation [3], albeit within the larger uncertainties of the latter.

In the same way we obtain the mass splitting $\Delta_\Lambda(m_s)$ where the light quark mass is extrapolated to the strange quark mass. The data fitted are shown in fig. 3b, and the result of the extrapolations described above is

$$\Delta_\Lambda(m_s) = 597 \pm 91 \pm 24 \text{ MeV}, \quad (7)$$

with the same meaning of errors. Instead of looking directly at the splitting at the strange quark mass, one may consider the ratio

$$r = \frac{\Delta_\Lambda(m_s)}{\Delta_\Lambda(m_u)}, \quad (8)$$

which is expected to have an even weaker $a$-dependence. Indeed the ratio for the different $\beta$ values shown in fig. 3c follows a "universal curve" with quite small statistical errors. A linear fit to the (weak) mass dependence yields

$$r = 1.25 \pm 0.03 \pm 0.05. \quad (9)$$

This ratio represents the change in the $\Lambda_b$ mass when replacing the $u$ quark by an $s$ quark.
Ξ Splitting. The mass splitting for the Ξ baryon is investigated using the same techniques as for the Λ. Table 3 displays the results after extrapolation of the light quark to the d and s mass respectively. We then convert all data to physical units, and plot $\Delta_\Xi$ vs. $1/M_P$ at the chiral limit in fig. 4. In this case the data show a statistically significant $a$-dependence, especially for heavy masses. We extrapolate to the continuum limit as above for pseudoscalar masses $M_P$ below the charm mass. We use the same ansatz as in the case of $\Delta_\Lambda$ to fit the $1/M_P$ dependence of $\Delta_\Xi$ and obtain:

$$\Delta_\Xi = -90 \pm 170 \text{ MeV} ,$$

This mass shift together with the experimental value for $M_B$ determines

$$M_\Xi = 10.45 \pm 0.17 \text{ GeV} ,$$

for the physical Ξ-b mass.

Another possibility to compute the Ξ-b mass, is to consider the ratio $R'_{\Xi}(t) = C_\Xi(t)/C_P^{hh}(t)$, which should yield the splitting between the Ξ-b mass and the $\Upsilon$-meson mass. We evaluated this quantity but the resulting plateaus turned out to be of worse quality than those for the other channel studied; this is due to the fact that smearing was applied only to light quarks, and so the heavy-heavy channels suffer from relevant contamination by higher-mass states.

4 Discussion

The mass splitting technique is a viable method to compute the Λ-b mass on the lattice. Both the lattice spacing dependence of the mass splitting and its dependence on the heavy quark mass are weak. Thus an extrapolation to the continuum and to the b-quark mass is possible. Our actual value of $M_{\Lambda_b} = 5728 \pm 144 \pm 18 \text{ MeV}$ can be compared to the value 5630 MeV suggested by Martin et al. within the naive quark model approach [4].

Experimentally, the determination of the Λ-b mass has a somewhat controversal history ever since 1981 [12]. Recently, the UA1 collaboration has measured the mass from 16 events in the decay channel $J/\Psi \Lambda$. It is an open question, why this decay channel has not been observed in the CDF experiment.
is \[ M_{\Lambda_b} = 5640 \pm 50 \pm 30 \text{MeV}. \] The DELPHI collaboration is presently quoting \[ M_{\Lambda_b} = 5635^{+38}_{-29} \pm 4 \text{MeV}, \] which is based on one candidate event in the $\Lambda_c^+\pi^-$ and in the $D^0p\pi^-$ decay modes. These numbers are in agreement with our result.

For $M_{\Lambda_c}$ we obtain $2433 \pm 88 \pm 18 \text{MeV}$, which is in rough accord with the experimental value of $2285 \text{MeV}$ \[12\]. Looking at the light quark dependence we found a 20% increase as we lift the quark mass from the chiral limit to the strange quark mass. Finally, an estimate for the $\Xi_b$ mass is given in eq.(11).

Our errors do include – as the dominant part – the uncertainty induced by an extrapolation to the continuum limit. Nevertheless, it is desirable to further check these extrapolations through simulations with higher lattice resolutions and/or different lattice actions.
