Abstract

**Background:** Enterotoxigenic *Escherichia coli* (ETEC) is a major diarrheal pathogen in developing countries, where it accounts for millions of infections and hundreds of thousands of deaths annually. While vaccine development to prevent diarrheal illness due to ETEC is feasible, extensive effort is needed to identify conserved antigenic targets. Pathogenic *Escherichia coli*, including ETEC, use the autotransporter (AT) secretion mechanism to export virulence factors. AT proteins are comprised of a highly conserved carboxy terminal outer membrane beta barrel and a surface-exposed amino terminal passenger domain. Recent immunoproteomic studies suggesting that multiple autotransporter passenger domains are recognized during ETEC infection prompted the present studies.

**Methodology:** Available ETEC genomes were examined to identify AT coding sequences present in pathogenic isolates, but not in the commensal *E. coli* HS strain. Passenger domains of the corresponding autotransporters were cloned and expressed as recombinant antigens, and the immune response to these proteins was then examined using convalescent sera from patients and experimentally infected mice.

**Principal Findings:** Potential AT genes shared by ETEC strains, but absent in the *E. coli* commensal HS strain were identified. Recombinant passenger domains derived from autotransporters, including Ag43 and an AT designated pAT, were recognized by antibodies from mice following intestinal challenge with H10407, and both Ag43 and pAT were identified on the surface of ETEC by flow cytometry. Likewise, convalescent sera from patients with ETEC diarrhea recognized Ag43 and pAT, suggesting that these proteins are expressed during both experimental and naturally occurring ETEC infections and that they are immunogenic. Vaccination of mice with recombinant passenger domains from either pAT or Ag43 afforded protection against intestinal colonization with ETEC.

**Conclusions:** Passenger domains of conserved autotransporter proteins could contribute to protective immune responses that develop following infection with ETEC, and these antigens consequently represent potential targets to explore in vaccine development.

Introduction

Enterotoxigenic *Escherichia coli* (ETEC) are a major cause of diarrheal illness in developing countries where these organisms cause hundreds of millions of infections and an estimated 300,000–500,000 deaths in young children each year [1]. ETEC are perennially by far the most common cause of traveler's diarrhea [2]. Disease caused by ETEC is highly endemic in regions plagued by inadequate sanitation and a lack of clean drinking water, and prevention of ETEC is a high priority [1,3]. ETEC are genetically heterogeneous pathogens that share the ability to colonize the small intestine where they deliver the cholera toxin-like heat-labile toxin (LT) and/or small peptide heat-stable (ST) toxins that ultimately result in diarrhea [4].

In the classic paradigm for ETEC pathogenesis, small intestinal colonization requires plasmid-encoded colonization factors (CFs) [4]. A variety of more than 25 antigenically distinct fimbrial, or fibrillar CFs have been described to date [5,6]. These antigens, along with LT, remain central to ETEC vaccine development [7]. However, CF antigens are not appreciably cross-protective, and
many ETEC strains do not appear to produce CFs [8,9]. Moreover, LT alone (or the homologous cholera toxin) do not many ETEC strains do not appear to produce CFs [8,9]. Moreover, LT alone (or the homologous cholera toxin) do not seem to be immunogenic and protective in an animal model, suggesting that conserved AT molecules contribute to protective immune responses that follow natural ETEC infection and offering new potential targets for vaccines.}

diarrhea, accounting for an estimated 300,000–500,000 deaths each year, mostly in young children. There unfortunately is not yet a vaccine that can offer sustained, broad-based protection against ETEC. While most vaccine development effort has focused on plasmid-encoded finger-like ETEC adhesin structures known as colonization factors, additional effort is needed to identify conserved target antigens. Epidemiologic studies suggest that immune responses to uncharacterized, chromosomally encoded antigens could contribute to protection resulting from repeated infections. Earlier studies of immune responses to ETEC infection had identified a class of surface-expressed molecules known as autotransporters (AT). Therefore, available ETEC genome sequences were examined to identify conserved ETEC autotransporters not shared by the commensal E. coli H5 strain, followed by studies of the immune response to these antigens, and tests of their utility as vaccine components. Two chromosomally encoded ATs, identified in ETEC, but not in H5, were found to be immunogenic and protective in an animal model, suggesting that conserved AT molecules contribute to protective immune responses that follow natural ETEC infection and offering new potential targets for vaccines.

**Methods**

**Bacterial strains and plasmids**

A complete list of strains and plasmids employed in these studies is included in table 1. ETEC strains H10407 and E24377A were originally provided by Marcia Wolf and Stephen Savarino, respectively, from cGMP lots maintained at Walter Reed Army Institute of Research.

**In silico analyses**

A number of parallel bioinformatics approaches were used to identify candidate AT genes in recently sequenced ETEC strains. Strains B7A and E24377A were searched for highly conserved autotransporter domains using the Pfam database including the autotransporter beta domain (http://pfam.sanger.ac.uk//family/ PF03797/) and the pertactin domain (http://pfam.sanger.ac.uk//family/PF03212). The resulting sequences containing these domains were used to identify additional autotransporters in the genome of ETEC strain H10407 available in un-annotated form via the Sanger Institute (http://www.sanger.ac.uk/Projects/E.coli_H10407/), which was facilitated by interrogating the available sequence using the National Microbial Pathogen Database Resource (NMPDR) [30] on the Rapid Annotation Subsystem Technology (RAST) server (http://RAST.nmpdr.org/) [31]. SignalP (http://www.cbs.dtu.dk/services/SignalP/) was used to identify potential signal peptide encoding regions of the predicted AT coding sequences. BLASTP (http://blast.ncbi.nlm.nih.gov/Blast.cgi) and Pfam domain searches of each putative AT peptide were used to define the conserved beta barrel transport domain (TIGR01414, and pfam03797, in the NCBI Conserved Domain Database http://www.ncbi.nlm.nih.gov/Structure/cdd/cdd.shtml and Pfam databases, respectively). Peptide sequence alignments of AT proteins common to the three ETEC strains used ClustalW [32] and MUSCLE [33] alignment algorithms performed locally (Mac OS 10.5.3) with an additional alignment plug-in (v1.06) for CLC Main Workbench software (v 5.5).

**Molecular cloning of autotransporter passenger domains**

Regions corresponding to the majority of each passenger domain (region between the end of the putative signal peptide encoding sequence and the beginning of the beta barrel domain) were amplified using primers bearing attB flanking sequences by high fidelity PCR (Platinum PCR SuperMix, Invitrogen). A complete list of primers used in these studies is included in table 2. Resulting amplicons were agarose gel-purified (Ultra Clean 15, MOBIO). Amplicons containing attB flanking sequences were cloned by recombination with the lambda attP sites on the entry vector pDONR221 (BP Clonase II, Invitrogen), and transformed into DH10B One Shot ccdB Survival T1 Chemically Competent E. coli (Invitrogen). Colonies were selected and patched onto kanamycin and chloramphenicol plates. Plasmid DNA extracted from kanamycin-resistant, chloramphenicol-sensitive colonies was analyzed by restriction digest to confirm presence of the

**Author Summary**

Diarrheal diseases are responsible for more than 1.5 million deaths annually in developing countries. Enterotoxigenic E. coli (ETEC) are among the most common bacterial causes of diarrhea, accounting for an estimated 300,000–500,000 deaths each year, mostly in young children. There unfortunately is not yet a vaccine that can offer sustained, broad-based protection against ETEC. While most vaccine development effort has focused on plasmid-encoded finger-like ETEC adhesin structures known as colonization factors, additional effort is needed to identify conserved target antigens. Epidemiologic studies suggest that immune responses to uncharacterized, chromosomally encoded antigens could contribute to protection resulting from repeated infections. Earlier studies of immune responses to ETEC infection had identified a class of surface-expressed molecules known as autotransporters (AT). Therefore, available ETEC genome sequences were examined to identify conserved ETEC autotransporters not shared by the commensal E. coli H5 strain, followed by studies of the immune response to these antigens, and tests of their utility as vaccine components. Two chromosomally encoded ATs, identified in ETEC, but not in H5, were found to be immunogenic and protective in an animal model, suggesting that conserved AT molecules contribute to protective immune responses that follow natural ETEC infection and offering new potential targets for vaccines.
appropriate insert. pDONR221 entry clones were then recombined with pDEST17 (LR Clonase II) placing the passenger domains in-frame with an amino-terminal polyhistidine tag in the resulting expression plasmid. Cloning reactions were used to transform DH5α to ampicillin resistance. Plasmid DNA from ampicillin-resistant, chloramphenicol-sensitive colonies was analyzed first by restriction endonuclease digestion, then sequenced using T7 promoter primer to confirm that the 6His- and passenger encoding sequences were placed in-frame. Resulting plasmids were then used to transform E. coli DH5α strains for approximately 3 hours to an OD600 of approximately 0.6, then 100 ml of fresh media, cultures were grown at 37°C for subsequent processing. Pellets were thawed on ice, and resuspended in binding buffer containing 20 mM Tris, 2 mM EDTA, 0.02%. After approximately 2 hours, cultures were centrifuged for 10,000 uC, 10,000 rpm for approximately 3 hours to an OD600 of approximately 0.6, then induced by the addition of L-arabinose to a final concentration of 0.02%. After approximately 2 hours, cultures were centrifuged for 5 minutes (4°C, 10,000 xg), and the resulting pellet saved and frozen at -80°C for subsequent processing.

Production of recombinant polyhistidine-tagged passenger proteins

To produce recombinant polyhistidine-tagged passenger proteins cultures of BL21-A1 containing pDEST17-encoded 6His-passen-ger clones were grown overnight at 37°C in Luria broth containing ampicillin (100 µg/ml). After diluting 1:100 in 100 ml of fresh media, cultures were grown at 37°C, 225 rpm for approximately 3 hours to an OD600 of approximately 0.6, then induced by the addition of L-arabinose to a final concentration of 0.02%. After approximately 2 hours, cultures were centrifuged for 5 minutes (4°C, 10,000 xg), and the resulting pellet saved and frozen at -80°C for subsequent processing.

Forward primers begin with sequence containing attB1 sites (underlined) and additional nucleotides (gg) to place following sequence in-frame with polyhistidine coding sequence in ultimate expression plasmid followed by gene-specific target sequences (...xxx-3'). Reverse primers begin with sequence containing attB2 sites (underlined) followed by stop codon (ttata), then gene-specific target sequence.

in larger scale by using Ni-Sepharose columns (HisTrap HP, GE Healthcare). Proteins were eluted over an imidazole gradient produced on a low-pressure chromatography system (BioLogic LP, BioRad). Purity of recombinant proteins was assessed by SDS-PAGE. Where necessary, fractions containing the protein of interest were further purified by ion exchange (HiTrap Q) or by SDS-PAGE and subsequent electrophoresis (Mini Whole Gel Eluter, BioRad).

Antibody production and affinity purification

Polyclonal rabbit antisera were produced as previously described (Rockland Immunochemicals, Gilbertsville, PA). Mouse polyclonal antibodies were obtained upon sacrifice of mice following completion of intranasal immunization with either adjuvant control or adjuvant and recombinant protein of interest as described below. Antibodies were affinity-purified as previously described [13,34]. Briefly, antibodies were absorbed onto immobilized antigen of interest on nitrocellulose, then eluted in 100 mM glycine, pH 2.5 followed by neutralization with 1 M Tris, pH 8.0.

Immunassays

To detect polychistidine-tagged rATp proteins transferred onto nitrocellulose, blocking was performed for one hour in 5% skim milk in tris-buffered saline (pH 7.2) containing 0.05% Tween-20 (TBS-T), and subsequent immunoblottings used purified rabbit polyclonal anti-His scum (1:500) and goat anti-rabbit immunoglobulin G (Fc)-Horseradish peroxidase (HRP) (1:10,000). All wash and incubation steps were performed in Tris-Buffered Saline (pH 7.2)- 0.05% Tween 20. Detection used luminol-based chemiluminescent substrate.

Assessment of immune responses to individual rATp proteins was carried out in a similar fashion using pooled primary convalescent sera (1:500) from mice following infection with ETEC strain H10407. Pooled, pre-immune sera (1:500) from the same mice was used as a primary antibody control. Sera obtained from ETEC-infected children (ICDDR,B) Dhaka, Bangladesh, and uninfected (age-matched) controls (LeBonheur Children’s Medical Center, Memphis, TN), were tested at a 1:2048 dilution. Primary antibody binding was detected using an HRP-labeled secondary (anti-mouse or anti-human) antibody that detects IgA, IgM and IgG (total Ab) and developed using sensitive chemiluminescent substrate (SuperSignal West Femto, Thermo Scientific).

Kinetic ELISA assays were performed as previously described [24]. For an in-depth comparison, kinetic and standard end-point ELISA techniques, the reader is referred to an earlier review available at http://www.biokem.com/resources/docs/KinetiAppNoteFinal.pdf [35]. ELISA wells were coated overnight at 4°C with (100 μl/well) of individual rATp proteins diluted to a final concentration of 4 μg/ml in 0.1 M NaHCO3 buffer (pH 8.6). Plates were washed three times with TBS-T, blocked with TBS-T containing 1% BSA (Blocker, Thermo Scientific) for 1 hour at 37°C. After washing briefly with TBS-T, plates were incubated with dilutions of primary antibody in TBS-T/1% BSA for 1 hour at 37°C, and again washed as above. Next, plates were incubated (1 h, 37°C) with goat anti-human or goat anti-mouse secondary antibody, which recognizes IgA, IgM, and IgG, at a final concentration of 1:10000 in TBS-T-BSA. After washing, plates were developed with TMB (3,3’,5,5’-Tetramethylbenzidine) peroxidase substrate (Kirkgaard and Perry Laboratories). Kinetic absorbance measurements [36] were determined at 650 nm, acquired at 60 second intervals (Molecular Devices Spectramax 340PC microplate reader). SoftMax Pro v5.0.1 was used for data recording and processing and the rate of substrate development was expressed as the Vmax in milli-units/min.

Immunization of mice

Mice were vaccinated intranasally with candidate antigens as previously described [37]. Briefly, groups of 10 ICR [38] mice received either IVX908 (Protollin®) [39] (7.5 μg) alone (controls), or IVX908 (7.5 μg) + rATp domains (20 μg) on days 0, 14, 28. Sera were collected on day 0 prior to immunization (pre-immune) and again 7–14 days after the final vaccination (post-immune). Prior to bacterial challenge (day 42), 5–6 fresh fecal pellets were collected from each mouse and immediately suspended in 1.5 ml of extraction buffer containing Tris (10 mM), NaCl (100 mM), Tween-20 (0.05%), and sodium azide (3 mM) pH 7.4.

Intestinal colonization studies

Approximately 1 week after completion of the immunization schedule, mice were challenged with βββ76, a derivative of ETEC H10407 containing a KmR marker in the lacZ gene as previously described [37,40]. Two independent challenge studies were completed; each involved a total of 30 mice including 10 controls (IVX908 only), and groups of 10 mice vaccinated with either of the two rATp proteins. Briefly, mice were treated with streptomycin (5 g/liter) in their drinking water to eliminate colonization resistance from competing normal enteric flora. Food was then withheld 12 hours prior to ETEC challenge and sterile water was used to replace the streptomycin solution. All mice received cimetidine (30 mg/kg via intraperitoneal injection) 2 hours prior to administration of bacteria. Mice were then challenged by gavage administration of bacterial strain βββ76 with total dose between 10⁵ and 10⁷ cfu/mouse. Previous studies have demonstrated that at 24 hours after inoculation with ETEC in the murine model, the number of colonizing colony forming units in the small intestine parallel values obtained at later time points (72 hours) [38]. Therefore, in these studies, approximately 24 hours after challenge mice were sacrificed, samples of ileum were harvested, then solubilized in saponin solution to release bacteria, and finally plated onto Luria agar plates containing kanamycin (25 μg/ml). Colonies were counted after incubation overnight at 37°C. Intestinal lysates with no bacteria recovered were assigned a value of 1 cfu (the lower limit of detection) as previously described [37]. Care was taken to minimize the use of animals in these experiments where possible. When necessary, appropriate steps were taken to ameliorate suffering of mice during vaccination and testing. The Institutional Animal Care and Use Committees of the University of Tennessee Health Sciences Center, and the VA Medical Center approved studies presented here. All procedures involving mice complied with Public Health Service guidelines, and The Guide for the Care and Use of Laboratory Animals.

Flow cytometry

To evaluate surface expression of autotransporter passenger domains, suspensions of H10407 in phosphate buffered saline (PBS, pH 7.2) were first fixed with 2% paraformaldehyde for 15 minutes. After washing twice with PBS, cells were blocked with 1% BSA in PBS for 30 minutes. The resulting cell suspension was incubated with either pre- or post-immune mouse sera (diluted 1:50 in blocking buffer) for 1 hour at room temperature (RT). After washing three times with PBS, cells were incubated with Alexa-Fluor (488)-labeled anti-mouse IgG [1:250] for 1 hour at RT, washed three times, and resuspended in PBS. Analysis of cell-bound fluorescence by flow cytometry used a BD FACSCalibur 4-color, dual-laser flow cytometer equipped with a FACStation data management system.
Results

Identification of additional ETEC autotransporter genes

In silico analysis of available ETEC genomes using searches for one or more of the known highly conserved AT domains identified multiple autotransporters in the genome of each ETEC strain. From these, we selected AT genes that were present in ETEC, but absent in the recently sequenced E. coli HS commensal isolate [41], for additional study (table 3). All three genomes shared at least one copy of both antigen43, and the pAT autotransporter genes (figure 1). Similar to other pathovars [42], we identified two copies of the agn43 gene in both H10407, and E24377A, but a single copy in B7A. The amino acid sequence of the passenger domains of these Ag43 molecules was highly conserved (supporting figure S1a), while the pAT passenger domains exhibited approximately 70% identity and 80% similarity (supporting figure S1b).

Although genes encoding proteins similar to pAT were found in the Enterobacteriaceae by BLAST searches of the prototype pAT molecule from H10407 (UniProt designation E3PFJ1) in the UniprotKB database, and were widely distributed among various pathovars of E. coli as well as Salmonella, and Shigella species (taxonomic distribution of these proteins is included in supporting figure S2), only those in E. coli exhibited more than 80% identity. As demonstrated in table 4, pAT homologues were identified in other diarrheagenic E. coli pathotypes including enterohemorrhagic strains (EHEC), enteropathogenic isolates (EPEC), and uropathogenic E. coli (UPEC), and extraintestinal pathogenic E. coli (ExPEC) isolated from meningitis. However, we also identified potential pAT homologues in non-HS commensal isolates from humans [43] as well as animals [44], suggesting that while pAT may not be essential for commensalism, it is not unique to pathogenic strains.

Surface expression of autotransporter passenger domains

Passenger domains of autotransporter proteins are exported to the bacterial surface where they may be cleaved and appear in the supernatant as in the case of EatA [14], or remain largely associated with bacterial cell surface as has been described for antigen 43 [42]. Antibodies raised against the recombinant passenger domains of Ag43, pAT, and EatA were tested in kinetic ELISA assays against the corresponding antigen as well as each of the other rATp domains. These studies revealed little or no cross-reactivity between antigens, suggesting that these proteins are immunologically distinct (figure 2a). Flow cytometry detected significant amounts of passenger domains of Ag43 and pAT associated with the bacterial cell surface of ETEC H10407, but not with the HS commensual strain (figure 2b). Likewise, pAT (figure 2c) and Ag43 (figure 2d) were identified on the surface of both the E24377A, and B7A ETEC strains.

notes:
1 recorded in the table are results obtained after BLASTP searches of the UniProt database with pAT from H10407, [http://www.uniprot.org/uniprot/E3PFJ1] using following parameters: database was UniProtKB; threshold = 0.0001; matrix = auto; low complexity regions filtered; gaps permitted.
2 (the top ten BLAST hits with established disease association metadata are included).

doi:10.1371/journal.pntd.0001428.g001
chose to focus here on the conserved, chromosomally encoded antigens, Ag43 and pAT. Subsequent studies demonstrated that both Ag43 and pAT are recognized during the course of human infections with ETEC (figure 3b, c).

Immunization with passenger proteins protects against ETEC colonization

To explore the utility of ETEC autotransporter proteins as vaccine candidates, we examined both the immunogenicity and protective efficacy of individual passenger domains for Ag43 and pAT in a murine model of ETEC infection. For these studies, we used the mucosal adjuvant Protollin (ivx908), a mixture of Shigella flexneri 2a LPS, and meningococcal outer membrane proteins. When delivered intranasally, Protollin (IVX908) elicits high levels of S. flexneri LPS-specific fecal IgA [48], and when combined as an adjuvant with other proteins, it promotes similarly robust immune responses to target antigens [39,49]. Immunization with either of the passenger domains for antigen 43 or pAT resulted in significant increases in total serum and fecal antibody levels in immunized mice relative to adjuvant-only (ivx908) controls (figure 4a–c). Importantly, immunization with either rPATp or rAg43p resulted in significant increases in fecal IgA directed at the respective antigens (figure 4d).

Immunization with either the antigen43 or pAT recombinant passenger domains provided significant protection against subsequent colonization with ETEC relative to adjuvant-immunized controls (figure 4e).

Discussion

Despite the global importance of enterotoxigenic E. coli infections, there is presently no vaccine against these pathogens...
transporters of the encoded member of the SPATE family (serine protease autoencoded TibA adhesin [55,56] protein and, EatA [14], a plasmid-encoded in ETEC pathogenesis. These include the chromosomally-encoded antigens [29], in addition to the plasmid-encoded CFs, that LT and perhaps other as yet unidentified chromosomally-encoded antigens [51,52]. In addition, many of the ETEC vaccine development effort to date has focused on the plasmid-encoded colonization factors (CFs). Unfortunately, antigenic heterogeneity and lack of appreciable cross protection between CFs have been impediments to this approach. To date, over twenty-five different CFs have been identified in ETEC [53], and many strains do not appear to make any of the known antigens [9,54]. Finally, carefully conducted epidemiologic studies of natural ETEC infections have suggested that LT and perhaps other as yet unidentified chromosomally-encoded antigens [29], in addition to the plasmid-encoded CFs, could be involved in protective immune responses.

Because we have recently demonstrated that several autotransporter proteins are recognized following experimental and natural ETEC infections [26], we chose to investigate the possible contribution of conserved chromosomally-encoded autotransporter proteins. The studies here suggest that the passenger domains of these autotransporters are recognized during the course of both experimental infections in animals and naturally-occurring infection in humans, and they validate recent immunoproteomic data obtained with the prototype H10407 ETEC strain using sera from infected mice or human convalescent sera [26].

Two additional autotransporters have previously been examined in ETEC pathogenesis. These include the chromosomally-encoded TibA adhesin [55,56] protein and, EatA [14], a plasmid-encoded member of the SPATE family (serine protease autotransporters of the Enterobacteriaceae). Both proteins are recognized during the course of experimental and naturally occurring infections [26]. Interestingly, the EatA protein appears modulate adhesion and colonization by digesting another recently described virulence molecule, the EtpA two-partner secretion exoprotein, an adhesin [12,13]. In turn, this modulation of adherence appears to be required for optimal delivery of heat-labile toxin (LT), a critical ETEC virulence molecule [57]. Although recent data suggest that both EtpA and EatA are reasonably conserved within the ETEC pathovar [52,58,59], the inherent plasticity of E. coli genomes, and the relative paucity of pathovar-specific virulence genes [51] identified to date suggests that additional effort is warranted to explore the potential utility of other highly conserved surface structures as vaccine candidates.

Although it is likely that autotransporters contribute the overall fitness of ETEC as a pathogen, neither of the proteins under study here has been shown to contribute to the pathogenesis of ETEC. Antigen 43 does however appear to be of importance in the pathogenesis of other E. coli pathovars, including uropathogenic E. coli (UPEC). In the urinary tract, Ag43 is expressed in intracellular biofilm-like pods [60], and particular variants appear to contribute to biofilm formation, and colonization of the urinary tract [61]. Similarly, immunoproteomic studies demonstrate that this antigen is also expressed [62] and recognized [63] during the course of E. coli urinary tract infections in humans.

Interestingly, in a study of an E. coli laboratory isolate, Ag43 contributed to biofilm formation in vitro, but did not appear to play a role in intestinal colonization in a murine model [64]. Nevertheless, some studies have suggested that specific Ag43 alleles segregate with diarrheagenic E. coli pathogens compared to other isolates from other pathovars [65], and that in general Ag43 was more commonly found in pathogens than in commensal strains.

Assessing the precise contribution of given antigens to the protective immune responses that develop following infection, or even following vaccination can be challenging [66,67]. While serologic responses to some CFs such as CFA/I have previously been correlated with a protective immune response to ETEC [28], it is likely that protection seen following natural infections reflects a composite response to a number of antigens.

Figure 3. Immunogenicity of autotransporter protein passenger domains. a. passenger domains of autotransporters pAT and Ag43 are recognized by during the course of experimental murine infection with ETEC H10407. Shown are metal affinity chromatography-purified antigens (MAC) used in analysis, followed by corresponding immunoblots using pooled sera obtained from mice before and after intestinal challenge with ETEC H10407. b. human ETEC convalescent sera (from patients infected with ETEC obtained at ICDDR,B), but not age-matched sera from uninfected controls (from LeBonheur Children’s Hospital, Memphis) recognize the ETEC H10407 autotransporter passenger domain of pAT (RAST designation 459). c. human ETEC convalescent sera, but not age-matched control sera recognize passenger domain of the ETEC H10407 autotransporter Ag43 (RAST designation 2318).

doi:10.1371/journal.pntd.0001428.g003
Additional studies will be needed to determine the utility of these antigens as well as other autotransporters in ETEC vaccines. The surface expression of the autotransporter passenger domains, their immunogenicity, and preliminary data presented here support the concept that this class of molecules could serve as protective antigens. Although the inherent plasticity of *E. coli* genomes [68] in general poses an impediment to vaccine development for ETEC, important data emerging from the DNA sequencing of multiple ETEC genomes does suggest that these pathogens maintain a core subset of relatively pathovar-specific genes, such as the *eatA* autotransporter gene, that might serve as suitable targets [52,59]. The suggestion that relatively few genes separate the ETEC pathovar from commensal *E. coli* [58] is an important consideration in moving forward with putative ETEC vaccines. The data presented here suggest that other autotransporters not unique to the ETEC pathovar contribute to intestinal colonization, a critical step in ETEC pathogenesis as well as the host immune response to these important pathogens. Whether the more widely distributed ATs such as Ag43 and pAT are truly dispensable for the commensal *E. coli* similar to the HS prototype strain will be an important consideration in designing both subunit and live-attenuated vaccine strategies.

Figure S2 Distribution of potential pAT-like proteins in the
Enterobacteriaceae. The distribution of potential pAT-like proteins was defined by BLASTP searches of Enterobacteriaceae with pAT from H10407 [http://www.uniprot.org/uniprot/
E3PFJ1] using the UniProtKB database (threshold E value of
0.0001; filtered for low regions of complexity). The degree of
identity varied from 89% (for enterohemorrhagic E. coli strain
d12009) to less than 50% for the other Enterobacteriaceae. Only E. coli
proteins were more than 80% identical to pAT. The closest homologues in E. coli are shown in table 4. (TIF)

Acknowledgments
IVX908 was acquired by Dr. James Dale from ID Biomedical, and was
kindly provided to our laboratory for use in these studies. We appreciate
the assistance of Ramy Aziz of the National Microbial Pathogen Data
Resource (NMPDR) in implementing RAST analysis of ETEC genomes.
