Abstract

We present a novel unsupervised feature representation learning method, Visual Commonsense Region-based Convolutional Neural Network (VC R-CNN), to serve as an improved visual region encoder for high-level tasks such as captioning and VQA. Given a set of detected object regions in an image (e.g., using Faster R-CNN), like any other unsupervised feature learning methods (e.g., word2vec), the proxy training objective of VC R-CNN is to predict the contextual objects of a region. However, they are fundamentally different: the prediction of VC R-CNN is by using causal intervention: \( P(Y|do(X)) \), while others are by using the conventional likelihood: \( P(Y|X) \). This is also the core reason why VC R-CNN can learn “sense-making” knowledge like chair can be sat — while not just “common” co-occurrences such as chair is likely to exist if table is observed. We extensively apply VC R-CNN features in prevailing models of three popular tasks: Image Captioning, VQA, and VCR, and observe consistent performance boosts across all the methods and tasks, achieving many new state-of-the-arts¹.

1. Introduction

“On the contrary, Watson, you can see everything. You fail, however, to reason from what you see.”

—Sherlock Holmes, The Adventure of the Blue Carbuncle

Today’s computer vision systems are good at telling us “what” (e.g., classification [21, 29], segmentation [20, 37]) and “where” (e.g., detection [53, 36], tracking [28, 32]), yet bad at knowing “why”, e.g., why is it dog? Note that the “why” here does not merely mean by asking for visual reasons — attributes like furry and four-legged — that are already well-addressed by machines; beyond, it means by asking for high-level commonsense reasons — such as dog barks [15] — that are still elusive, even for the Aristotelian and pre-Galilean philosophers [19, 56], not to mention for machines.

It is not hard to spot the “cognitive errors” committed by machines due to the lack of common sense. As shown in Figure 1, by using only the visual features, e.g., the prevailing Faster R-CNN [53] based Up-Down [2], machine usually fails to describe the exact visual relationships (the captioning example), or, even if the prediction is correct, the underlying visual attention is not reasonable (the VQA example). Previous works blame this for dataset bias without further justification [22, 42, 52, 7], e.g., the large concept co-occurrence gap in Figure 1; but here we take a closer look at it by appreciating the difference between the “visual” and “commonsense” features. As the “visual” only tells “what”/“where” about person or leg per se, it is just a more descriptive symbol than its correspondent English word; when there is bias, e.g., there are more person than leg regions co-occur with the word “ski”, the visual attention is thus more likely to focus on the person region. On the other hand, if we could use the “commonsense” features, the action of “ski” can focuses on the leg region.

Figure 1. Examples of “cognitive errors” in image captioning and VQA due to the dataset bias. The ratio \( J \) denotes the co-occurrence% in ground-truth text (captioning: captions, VQA: questions). By comparing with the Faster R-CNN [53] based features [2], our VC R-CNN features can correct the errors, e.g., more accurate visual relationships and visual attentions, by being more commonsense awareness.

¹https://github.com/Wangt-CN/VC-R-CNN
Figure 2. The illustration of why \( P(Y|do(X)) \) learns common sense while \( P(Y|X) \) does not. Thanks to intervention, \( P(Y|do(X)) \) can “borrow” objects from other images and “put” them into the local image, to perform further justifications if \( X \) truly causes \( Y \) regardless of the unobserved confounders, and thus alleviate the observational bias.

because of the common sense: we ski with legs.

We are certainly not the first to believe that visual features should include more commonsense knowledge, rather than just visual appearances. There is a trend in our community towards weakly-supervised learning features from large-scale vision-language corpus [39, 58, 59]. However, despite the major challenges in trading off between annotation cost and noisy multimodal pairs, common sense is not always recorded in text due to the reporting bias [64, 35], e.g., most may say “people walking on road” but few will point out “people walking with legs”. In fact, we humans naturally learn common sense in an unsupervised fashion by exploring the physical world, and we wish that machines can also imitate in this way.

A successful example is the unsupervised learning of word vectors in our sister NLP community [43, 11, 49]: a word representation \( X \) is learned by predicting its contextual word \( Y \), i.e., \( P(Y|X) \) in a neighborhood window. However, its counterpart in our own community, such as learning by predicting surrounding objects or parts [12, 41], is far from effective in down-stream tasks. The reason is that the commonsense knowledge, in the form of language sentences, has already been recorded in discourse; in contrast, once an image has been taken, the explicit knowledge why objects are contextualized will never be observed, so the true common sense that \( \text{causes} \) the existence of objects \( X \) and \( Y \) might be confounded by the spurious observational bias, e.g., if keyboard and mouse are more often observed with table than any other objects, the underlying common sense that keyboard and mouse are parts of computer will be wrongly attributed to table.

Intrigued, we perform a toy MS-COCO [34] experiment with ground-truth object labels — by using a mental apparatus, intervention, that makes us human [48] — to screen out the existence of confounders and then eliminate their effect. We compare the difference between association \( P(Y|X) \) and causal intervention \( P(Y|do(X)) \) [47]. As illustrated in Figure 2, you can intuitively understand the intervention as the following deliberate experiment: 1) “borrow” objects \( Z \) from other images, 2) “put” them around \( X \) and \( Y \), then 3) test if \( X \) still causes the existence of \( Y \) given \( Z \). The “borrow” and “put” is the spirit of intervention, which implies that the chance of \( Z \) is only dependent on us (probably subject to a prior), but independent on \( X \) or \( Y \). By doing so, as shown in Figure 3, \( P(\text{sink}|\text{do(dryer)}) \) is lower because the most common restroom context such as towel is forced to be seen as fair as others. Therefore, by using \( P(\text{sink}|\text{do(dryer)}) \) as the learning objective, the bias from the context towel will be alleviated.

More intriguing, \( P(\text{person}|\text{do(toilet)}) \) is higher. Indeed, person and toilet co-occur rarely due to privacy. However, human’s seeing is fundamentally different from machine’s because our instinct is to seek the causality behind any association [48] — and here comes the common sense. As opposed to the passive observation \( P(Y|X) \): “How likely I see person if I see toilet”, we keep asking “Why does seeing toilet eventually cause seeing person?” by using \( P(Y|do(X)) \). Thanks to intervention, we can increase \( P(Y|do(X)) \) by “borrowing” non-local context that might not be even in this image, for the example in Figure 2, objects usable by person such as chair and handbag — though less common in the restroom context — will be still fairly “borrowed” and “put” in the image together with the common sink. Therefore, the toilet region can implicitly learn the common sense: usable. We will revisit this example formally in Section 3.1.

So far, we are ready to present our unsupervised region feature learning method: Visual Commonsense R-CNN (VC R-CNN), as illustrated in Figure 4, which uses Region-based Convolutional Neural Network (R-CNN) [53] as the visual backbone, and the causal intervention as the training objective. Besides its novel learning fashion, we also design a novel algorithm for the do-operation, which is an effective approximation for the imaginative intervention (cf. Section 3.2). The delivery of VC R-CNN is a region fea-
Figure 4. The overview of VC R-CNN. Any R-CNN backbone (e.g., Faster R-CNN [53]) can be used to extract regions of interest (RoI) on the feature map. Each RoI is then fed into two sibling branches: a Self Predictor to predict its own class of \( x \), and a Context Predictor to predict its context labels, e.g., \( y^c \), with our Do intervention. The architecture is trained end-to-end with a multi-task loss.

We apologize humbly to disclaim that VC R-CNN provides a philosophically correct definition of “visual common sense”. We only attempt to step towards a computational definition in two intuitive folds: 1) common: unsupervised learning from the observed objects, and 2) sense-making: pursuing the causalities hidden in the observed objects. VC R-CNN not only re-thinks the conventional likelihood-based learning in our CV community, but also provides a promising direction — causal inference [48] — via practical experiments.

2. Related Work

Multimodal Feature Learning. With the recent success of pre-training language models (LM) [11, 51, 49] in NLP, several approaches [39, 58, 59, 9] seek weakly-supervised learning from large, unlabelled multi-modal data to encode visual-semantic knowledge. However, all these methods suffer from the reporting bias [64, 35] of language and the great memory cost for downstream fine-tuning. In contrast, our VC R-CNN is unsupervised learning only from images and the learned feature can be simply concatenated to the original representations.

Un-/Self-supervised Visual Feature Learning [13, 61, 41, 27, 74]. They aim to learn visual features through an elaborated proxy task such as denoising autoencoders [6, 65], context & rotation prediction [12, 16, 31]. The context prediction is learned from correlation while image rotation and augmentation can be regarded as applying the random controlled trial [48], which is active and non-observational (physical); by contrast, our VC R-CNN learns from the observational causal inference that is passive and observational (imaginative).

Visual Common Sense. Previous methods mainly fall into two folds: 1) learning from images with commonsense knowledge bases [64, 71, 55, 57, 67, 75] and 2) learning from videos [17]. However, the first one limits the common sense to the human-annotated knowledge, while the latter is essentially, again, learning from correlation.

Causality in Vision. There has been a growing amount of efforts in marrying complementary strengths of deep learning and causal reasoning [47, 46] and have been explored in several contexts, including image classification [8, 38], reinforcement learning [44, 10, 5] and adversarial learning [26, 24]. Lately, we are aware of some contemporary works on visual causality such as visual dialog [50] and scene graph generation [60]. Different from their task-specific causal inference, VC R-CNN offers a generic feature extractor.

3. Sense-making by Intervention

We detail the core technical contribution in VC R-CNN: causal intervention and its implementation.

3.1. Causal Intervention

As shown in Figure 5 (left), our visual world exists many confounders \( z \in Z \) that affects (or causes) either \( X \) or \( Y \), leading to spurious correlations by only learning from the likelihood \( P(Y|X) \). To see this, by using Bayes rule:

\[
P(Y|X) = \sum_z P(Y|X, z) P(z|X),
\]

where the confounder \( Z \) introduces the observational bias via \( P(z|X) \). For example, as recorded in Figure 6, when \( P(z=sink|X=toilet) \) is large while \( P(z=chair|X=toilet) \) is small, most of the likelihood sum in Eq. (1) will be credited to \( P(Y=person|X=toilet, z=sink) \), other than \( P(Y=person|X=toilet, z=chair) \), so, the prediction from toilet to person will be eventually focused on sink rather than toilet itself, e.g., the
learned features of a region toilet are merely its surrounding sink-like features.

As illustrated in Figure 5 (right), if we intervene $X$, e.g., $do(X \rightarrow toilet)$, the causal link between $Z$ and $X$ is cut-off. By applying the Bayes rule on the new graph, we have:

$$P(Y|do(X)) = \sum_z P(Y|X, z) P(z). \tag{2}$$

Compared to Eq. (1), $z$ is no longer affected by $X$, and thus the intervention deliberately forces $X$ to incorporate every $z$ fairly, subject to its prior $P(z)$, into the prediction of $Y$. Figure 6 shows the gap between the prior $P(z)$ and $P(z|toilet)$, $z \in Z$ is the set of MS-COCO labels. We can use this figure to clearly explain the two interesting key results by performing intervention. Please note that $P(Y|X, z)$ remains the same in both Eq. (1) and Eq. (2).

Please recall Figure 3 for the sensible difference between $P(Y|X)$ and $P(Y|do(X))$. First, $P(person|do(toilet)) > P(person|toilet)$ is probably because $P(z|toilet) > P(z)$ is smaller than those such that $P(z|toilet) < P(z)$, i.e., the left grey area is smaller than the right grey area in Figure 6, making Eq. (1) smaller than Eq. (2). Second, we can see that $z$ making $P(z) < P(z|X)$ is mainly from the common restroom context such as sink, bottle, and toothbrush. Therefore, by using intervention $P(Y|do(X))$ as the feature learning objective, we can adjust between “common” and “sense-making”, and thus alleviate the observational bias.

Figure 7(a) visualizes the features extracted from MS-COCO images by using the proposed VC R-CNN. Promisingly, compared to $P(Y|X)$ (left), $P(Y|do(X))$ (right) successfully discovers some sensible common sense. For example, before intervention, window and leg features in red box are close due to the street view observational bias, e.g., people walking on street with window buildings; after intervention, they are clearly separated. Interestingly, VC R-CNN leg features are closer to head while window features are closer to wall. Similarly, the

**3.2. The Proposed Implementation**

To implement the theoretical and imaginative intervention in Eq. (2), we propose the proxy task of predicting the local context labels of $Y$’s RoI. For the confounder set $Z$, since we can hardly collect all confounders in real world, we approximate it to a fixed confounder dictionary $Z = [z_1, ..., z_N]$ in the shape of $N \times d$ matrix for practical use, where $N$ is the category size in dataset (e.g., 80 in MS-COCO) and $d$ is the feature dimension of RoI. Each entry $z_i$ is the averaged RoI feature of the $i$-th category samples in dataset. The feature is pre-trained by Faster R-CNN.

Specifically, given $X$’s RoI feature $x$ and its contextual $Y$’s RoI whose class label is $y^c$, Eq. (2) can be implemented as $\sum_z P(y^c|x, z) P(z)$. The last layer of the network for label prediction is the Softmax layer: $P(y^c|x, z) = \text{Softmax}(f_y(x, z))$, where $f_y(\cdot)$ calculates the logits for $N$ categories, and the subscript $y$ denotes that $f(\cdot)$ is parameterized by $Y$’s RoI feature $y$, motivated by the intuition that the prediction for $y^c$ should be characterized by $Y$. In summary, the implementation is defined as:

$$P(Y|do(X)) := \mathbb{E}_z[\text{Softmax}(f_y(x, z))]. \tag{3}$$

Note that $\mathbb{E}_z$ requires expensive sampling.

**Normalized Weighted Geometric Mean (NWGM).** We apply NWGM [68] to approximate the above expectation.
CNN takes an entire image as input and then generates region bounding box proposals from a CNN backbone (e.g., ResNet101 [21]). Then, for each ground-truth bounding box, the RoIAlign Layer is utilized to extract the object level representation. Finally, each two RoI features \(x\) and \(y\) eventually branch into two sibling predictors: Self Predictor with a fully connected layer to estimate each object class, while Context Predictor with the approximated do-calculus in Eq. (3) to predict the context label.

**Training Objectives.** The Self-Predictor outputs a discrete probability distribution \(p = (p[1], ..., p[N])\) over \(N\) categories (note that we do not have the “background” class). The loss can be defined as \(L_{sclf}(p, x^c) = -log(p[x^c])\), where \(x^c\) is the ground-truth class of RoI \(X\). The Context Predictor loss \(L_{ext}\) is defined for each two RoI feature vectors. Consider \(X\) as the center object while \(Y_i\) is one of the \(K\) context objects with ground-truth label \(y_i^c\), the loss is \(L_{ext}(p_i, y_i^c) = -log(p_i[y_i^c])\), where \(p_i\) is calculated by \(p_i = P(Y_i|do(X))\) in Eq. (3) and \(p_i = (p_i[1], ..., p_i[N])\) is the probability over \(N\) categories. Finally, the overall multitask loss for each RoI \(X\) is:

\[
L(X) = L_{sclf}(p, x^c) + \frac{1}{K} \sum_i L_{ext}(p_i, y_i^c).
\]

**Feature Extractor.** We consider VC R-CNN as a visual commonsense feature extractor for any region proposal. Then the extracted features are directly concatenated to the original visual feature utilized in any downstream tasks. It is worth noting that we do NOT recommend early concatenations for some models that contain a self-attention architecture such as AoANet [23]. The reasons are two-fold. First, as the computation of these models are expensive, early concatenation significantly slows down the training. Second, which is more crucial, the self-attention essentially and implicitly applies \(P(Y|X)\), which contradicts to causal intervention. We will detail this finding in Section 5.4.

5. Experiments

5.1. Datasets

We used the two following datasets for unsupervised learning VC R-CNN.

**MS-COCO Detection** [34]. It is a popular benchmark dataset for classification, detection and segmentation in our community. It contains 82,783, 40,504 and 40,775 images for training, validation and testing respectively with 80 annotated classes. Since there are 5K images from downstream image captioning task which can be also found in MS-COCO validation split, we removed those in training. Moreover, recall that our VC R-CNN relies on the context prediction task, thus, we discarded images with only one annotated bounding box.

**Open Images** [30]. We also used a much larger dataset called Open Images, a huge collection containing 16M
Table 1. The image captioning performances of representative two models with ablative features on Karpathy split. The metrics: B4, M, R and C denote BLEU@4, METEOR, ROUGE-L and CIDEr-D respectively. The grey row highlight our features in each model. AoANet† indicates the AoANet without the refine encoder. Note that the Origin and Obj share the same results in MS-COCO and Open Images since they do not contain our new trained features.

Table 2. The performances of various single models on the online MS-COCO test server. Up-Down+VC and AoANet+VC are the short for concatenated on [2] in Up-Down and AoANet†.

Table 3. Hallucination analysis [54] of various models on MS-COCO Karpathy test split to measure object hallucination for image captioning. The lower, the better.

5.2. Implementation Details

We trained our VC R-CNN on 4 Nvidia 1080Ti GPUs with a total batch size of 8 images for 180K iterations (each mini-batch has 2 images per GPU). The learning rate was set to 0.0002 which was decreased by 10 at every 120K iteration and ResNet-101 was set to the image feature extraction backbone. We used SGD as the optimizer with weight decay of 0.0001 and momentum of 0.9 following [53]. To construct the confounder dictionary Z, we first employed the pre-trained official ResNet-101 model on Faster R-CNN with ground-truth boxes as the input to extract the RoI features for each object. For training on Open Images, we first trained a vanilla Faster R-CNN model. Then Z is built by making average on RoIs of the same class and is fixed during the whole training stage.

5.3. Comparative Designs

To evaluate the effectiveness of our VC R-CNN feature (VC), we present three representative vision-and-language downstream tasks in our experiment. For each task, a classic model and a state-of-the-art model were both performed for comprehensive comparisons. For each method, we used the following three ablative feature settings: 1) Obj: the features based on Faster R-CNN, we adopted the popular used bottom-up feature [2]; 2) Only VC: pure VC features; 3) +Det: the features from training R-CNN with single self detection branch without Context Predictor. “+” denotes the extracted features are concatenated with the original feature, e.g., bottom-up feature; 4) +Cor: the features from training R-CNN by predicting all context labels (i.e., correlation) without the intervention; 5) +VC: our full feature with the proposed implemented intervention, concatenated to the original feature. For fair comparisons, we retained all the settings and random seeds in the downstream task models. Moreover, since some downstream models may have different settings in the original papers, we also quoted their results for clear comparison. For each downstream task, we detail the problem settings, dataset and evaluation metrics as below.

Image Captioning. Image captioning aims to generate textual description of an image. We trained and evaluated on the most popular “Karpathy” split built on MS-COCO dataset, where 5K images for validation, 5K for testing, and the rest for training. The sentences were tokenized and changed to lowercase. Words appearing less than 5 times were removed and each caption was trimmed to a maximum of 16 words. Five standard metrics were applied for evaluating the performances of the testing models: CIDEr-D [63], BLEU [45], METEOR [4], ROUGE [33] and SPICE [1].

Visual Question Answering (VQA). The VQA task requires answering natural language questions according to the images. We evaluated the VQA model on VQA2.0 [18]. Compared with VQA1.0 [3], VQA2.0 has more question-image pairs for training (443,757) and validation (214,354), and all the question-answer pairs are balanced. Before training, we performed standard text pre-processing. Questions were trimmed to a maximum of 14 words and candidate answer set was restricted to answers appearing more than 8 times. The evaluation metrics consist of three pre-type accuracies (i.e., “Yes/No”, “Number” and “Other”).

Visual Commonsense Reasoning (VCR). In VCR, given
Results on Image Captioning. We compared our VC representation with ablative features on two representative approaches: Up-Down [2] and AoANet [23]. For Up-Down model shown in Table 1, we can observe that with our +VC trained on MS-COCO, the model can even outperform current SOTA method AoANet over most of the metrics. However, only utilizing the pure VC feature (i.e., Only VC) would hurt the model performance. The reason can be obvious. Even for human it is insufficient to merely know the common sense that “apple is edible” for specific tasks, we also need visual features containing objects and attributes (e.g., “what color is the apple”) which are encoded by previous representations. When comparing +VC with the +Det and +Cor without intervention, results also show absolute gains over all metrics, which demonstrates the effectiveness of our proposed causal intervention in representation learning. AoANet [23] proposed an “Attention on Attention” module on feature encoder and caption decoder for refining with the self-attention mechanism. In our experiment, we discarded the AoA refining encoder (i.e., AoANet) rather than using full AoANet since the self-attentive operation on feature can be viewed as an indiscriminate correlation against our do-expression. From Table 1 we can observe that our +VC with AoANet† achieves a new SOTA performance. We also evaluated our feature on the online COCO test server in Table 2. We can find our model also achieves the best single-model scores across all metrics outperforming previous methods significantly.

Moreover, since the existing metrics fall short to the dataset bias, we also applied a new metric CHAIR [54] to measure the object hallucination (e.g., “hallucinate” objects not in image). The lower is better. As shown in Table 3, we can see that our VC feature performs the best on both standard and CHAIR metrics, thanks to our proposed intervention that can encode the visual commonsense knowledge.

Results on VQA. In Table 4, we applied our VC feature on classical Up-Down [2] and recent state-of-the-art method MCAN [72]. From the results, our proposed +VC outperforms all the other ablative representations on three answer types, achieving the state-of-the-art performance. However, compared to the image captioning, the gains on VQA with our VC feature are less significant. The potential reason lies in the limited ability of the current question understanding, which cannot be resolved by “visual” common sense. Table 5 reports the single model performance of various models on both test-dev and test-standard sets. Although our VC feature is limited by the question understanding, we still receive the absolute gains by just feature concatenation compared to previous methods with complicated module stack, which only achieves a slight improvement.

Results on VCR. We present two representative methods R2C [73] and ViLBERT [39] in this emerging task on the validation set. Note that as the R2C applies the ResNet backbone for residual feature extraction, here for fair comparison we followed the uniform experimental settings and switched it to the bottom-up features. The re-implementation results are shown as the Obj model in Table 6. From the comparison with ablative visual representations, our +VC feature still shows the best performances similar to the above two tasks.
A man standing on skis in the snow. A man standing on skis on a snow covered slope. A plate of food on the table. A plate of food with a bowl of pasta. A group of benches sitting on a bench. A book sitting on top of a wooden bench. To evaluate the transfer ability to evaluate the transfer ability on Open Images.

Table 7. Ablation studies of our proposed intervention trained on MS-COCO and evaluated with CIDEr-D (captioning) and Accuracy (VQA) on Karpathy testset and VQA2.0 validation set.

| Component | Setting            | CIDEr-D | Accuracy |
|-----------|--------------------|---------|----------|
| Expectation | $E_{z}[z]$ | 128.9 | 67.2 |
| NCC       | w/o NCC | 131.6 | 67.7 |
| Dictionary | Random Dictionary | 127.5 | 66.9 |
|           | Context Dictionary | Unstable Training | |
| Fixed Dictionary | 131.6 | 67.7 |

Results on Open Images. To evaluate the transfer ability and flexibility of the learned visual commonsense feature, we also performed our proposed VC R-CNN on a large image detection collection. The results can be referred to Table 1&4&6. We can see that the performances are extremely close to the VC feature trained on MS-COCO, indicating the stability of our learned semantically meaningful representation. Moreover, while performing VCR with the dataset of movie clip, which has quite diverse distributions compared to the captioning and VQA built on MS-COCO, our VC R-CNN trained on Open Images achieves the reasonable better results.

5.5. Qualitative Analysis

We visualize several examples with our VC feature and previous Up-Down feature [2] for each task in Figure 9. Any other settings except for feature kept the same. We can observe that with our VC, models can choose more precise, reasonable attention area and explicable better performance.

5.6. Ablation Study

To evaluate our proposed intervention implementation, we carry out different settings for each module in our VC R-CNN and report results on captioning and VQA in Table 7. $E_{z}[z]$ denotes utilizing statistical $P(z)$ by counting from the dataset without attention. Random Dictionary denotes initializing the confounder dictionary by randomization rather than the average RoI feature, while the Context Dictionary encodes contexts in each image as a dynamic dictionary set. The default setting is the fixed confounder dictionary with our attention module and NCC, which gives the best results. We can observe that random dictionary and $E_{z}[z]$ would hurt the performance, which demonstrates the effectiveness of our implementation. Moreover, we can find that NCC refining just brings a little difference to the downstream task performance. The potential reason is that NCC just provides a qualitative prediction and may have deviation when applying on real-world visual feature. We will continue exploring NCC in the future work.

6. Conclusions

We presented a novel unsupervised feature representation learning method called VC R-CNN that can be based on any R-CNN framework, supporting a variety of high-level tasks by using only feature concatenation. The key novelty of VC R-CNN is that the learning objective is based on causal intervention, which is fundamentally different from the conventional likelihood. Extensive experiments on benchmarks showed impressive performance boosts on almost all the strong baselines and metrics. In future, we intend to study the potential of our VC R-CNN applied in other modalities such as video and 3D point cloud.

Acknowledgments We would like to thank all reviewers for their constructive comments. This work was partially supported by the NTU-Alibaba JRI and the Singapore Ministry of Education (MOE) Academic Research Fund (AcRF) Tier 1 grant.

Supplementary Material

In this Supplementary Material, we will further detail the following aspects omitted in the main paper. The detailed code guide and VC features can be referred to [https://github.com/Wangt-CN/VC-R-CNN](https://github.com/Wangt-CN/VC-R-CNN).

- Section A: the detailed derivation of the intervention in Section 3.1 Causal Intervention of the main paper.
- Section B: The details of our proposed implementation in Section 3.2 of the main paper.
- Section C: The details of the network architecture of our VC R-CNN in Section 4 in the main paper.
- Section D: more quantitative results of VC features concatenated on different Faster R-CNN based representations.
- Section E: more qualitative visualizations compared our VC features with previous bottom-up representations [1].

A. The Do-Expression

In our main paper, we give the do-expression Eq. (2) comparing with the Bayes rule in an intuitive way for easier understanding. In this section, we further formally explain and prove the intervention (do calculus) in causal theory which is applied in our VC R-CNN.

\[
P(Y|\text{do}(X)) = P_m(Y|X). \quad (\text{Definition}) \quad (1)
\]

Then the key to compute the causal effect lies in the observation \(P_m\), the manipulated probability, shares two essential properties with \(P\) (i.e., the original probability function that prevails in the preintervention model). First, the marginal probability \(P(Z = z)\) is invariant under the intervention, because the process determining \(Z\) is not affected by removing the arrow from \(Z\) to \(X\), i.e., \(P(z) = P_m(z)\). Second, the conditional probability \(P(Y|X, z)\) is invariant, because the process by which \(Y\) responds to \(X\) and \(Z\) remains the same, regardless of whether \(X\) changes spontaneously or by deliberate manipulation:

\[
P_m(Y|X, z) = P(Y|X, z). \quad (\text{Invariance}) \quad (2)
\]

Moreover, we can also use the fact that \(Z\) and \(X\) are independent under the intervention distribution. This tell us that \(P_m(z|X) = P_m(z)\). Putting these considerations together, we have:

\[
P(Y|\text{do}(X)) = P_m(Y|X)
= \sum_z P_m(Y|X, z) P_m(z|X) \quad (\text{Bayes Rule})
= \sum_z P_m(Y|X, z) P_m(z) \quad (\text{Independency})
= \sum_z P(Y|X, z) P(z),
\]

where \(P(Y|X, z)\) denotes the conditional probability given \(X\) and confounder \(z\) and \(P(z)\) is a prior probability of each object class.

The Eq. (3) is called the adjustment formula, which computed the association between \(X\) and \(Y\) for each value of \(Z\), then averages over all values. This procedure is referred to as “adjusting for \(Z\)” or “controlling for \(Z\)”. Then with this final expression, we can measure the casual effects between \(X\) to \(Y\) directly from the data, since it consists only of conditional probabilities.

Moreover, in the main paper to show the difference between Bayes Rule and Intervention clearly, we propose an example about \text{person} and \text{toilet} by comparing \(P(Z)\) and \(P(Z|\text{toilet})\) on partial labels. Here in the Supplementary Material we present the integrated figure for whole 80 MS-COCO labels on both \(P(Z)\), \(P(Z|X)\) and \(P(Y|X, Z)P(Z)P(Y|X, Z)P(Z|X)\) in Figure 2 & 3. From Figure 2 we can see that the do intervention achieves “borrow” and “put” by applying \(P(Z)\) to replace \(P(Z|X)\), which can be also regarded as a kind of method to alleviate the previous long tail distribution (blue line).

B. Our Proposed Implementation

B.1. Normalized Weighted Geometric Mean.

In our main paper we just give the application of Normalized Weighted Geometric Mean (NWGM) due to the limited space, here we present the detailed derivation and reader can
also refer to the [8]. Recall that in the main paper we have defined the RoI feature $x$ as the $X$, one of its context class label $y$ as $Y$. For the confounder set $Z$, we denote it as a global confounder dictionary $Z = [z_1, ..., z_N]$ in the shape of $N \times d$ matrix for practical use, where $N$ is the category size in dataset (e.g., 80 in MS-COCO) and $d$ is the feature dimension of $x$.

Here we first introduce the normalized weighted geometric mean in our softmax class label prediction:

$$NWGM[f_y(x, z)] = \frac{\prod_z \exp(f_y(x, z))^{p(z)}}{\sum_j \prod_z \exp(f_y(x, z))^{p(z)}}$$

$$= \frac{\exp(\mathbb{E}_z[f_y(x, z)])}{\sum_j \exp(\mathbb{E}_z[f_y(x, z)])}$$

$$= \text{Softmax}(\mathbb{E}_z[f_y(x, z)])$$

where $f_y(\cdot)$ calculates the logits for $N$ categories. Note that the subscript $y$ denotes that $f(\cdot)$ is parameterized by feature $y$, motivated by the heuristics that the context prediction task for RoI $Y$ is characterized by its visual feature. We can see that the most ingenious operation in Eq. (4) is to change the production $\prod$ to the sum $\sum$ by putting it into the exp. Moreover, from the results in [8, 2, 7], we know $NWGM[f_y(x, z)] \approx \mathbb{E}_z[\text{Softmax}(f_y(x, z))]$ under the softmax activation. Therefore Eq. (3) in the main paper can be further derived as:

$$P(Y|do(X)) \approx \text{Softmax}(\mathbb{E}_z[f_y(x)])$$. (5)

Furthermore, we use the linear model $f_y(x, z) = \mathbf{W}_1 x + \mathbf{W}_2 \cdot g_y(z)$, where $\mathbf{W}_1, \mathbf{W}_2 \in \mathbb{R}^{N \times d}$ denote the fully connected layer. Then the linear projection of the expectation of one variable equals to the linear projection of that and we can put $\mathbb{E}$ into the linear projection as $\text{Softmax}(\mathbf{W}_1 \mathbb{E}_z[x] + \mathbf{W}_2 \cdot \mathbb{E}_z[g_y(z)])$. Since the RoI representation $x$ remains the same, we can discard the $\mathbb{E}$ over $x$, i.e., $\text{Softmax}(\mathbf{W}_1 x + \mathbf{W}_2 \cdot \mathbb{E}_z[g_y(z)])$. That means the expectation of the outputs over all possible confounder $z$ can be simply computed by feedforward propagation with
the expectation vector $E_z [g_y(z)]$ as the input.

B.2. Neural Causation Coefficient (NCC)

Here we give a more detailed information about the usage of NCC and collider of our proposed implementations in the main paper. In our visual world sometimes there are no confounders in the structure like $X \rightarrow Z \leftarrow Y$ what we call “collider”, as shown in Figure 4. Felix Elwert and Chris Winship [4] have illustrated this junction using three features of Hollywood actors: Talent ($X$), Celebrity ($Z$), and Beauty ($Y$). Here we are asserting that both talent and beauty contribute to an actor’s success, but beauty and talent are completely unrelated to one another in the general population.

In this structure making the intervention on variable $Z$ (i.e., condition on $Z$) would create a spurious dependence between $X$ and $Y$. The reason is that if $X$ and $Y$ are independent to begin with, conditioning on $Z$ will make them dependent. For example, if we look only at famous actors (in other words, we observe the variable Celebrity = 1), we will see a negative correlation between talent and beauty: finding out that a celebrity is unattractive increases our belief that he or she is talented. This negative correlation is sometimes called collider bias or the “explain-away” effect. Therefore we cannot make the intervention as what we do before in the collider structure. For simplicity we would make a preliminary examination before training to eliminate the effect of collider in the whole dataset. We apply the neural causation inference model (NCC) [6] to detect the strong causal effect from $X \rightarrow Z$ and $Y \rightarrow Z$ with the RoI feature directly.

NCC has partly proven [6] to be efficient for transferring to real-world, visual cause-effect observational samples. Specifically, the $n$ synthetic observational samples $S_i = \{(x_{ij}, y_{ij})\}^{m_i}_{j=1}$ are drawn from an heteroscedastic additive noise model $y_{ij} = f_i(x_{ij}) + v_{ij}e_{ij}$ for all $j = 1, ..., m_i$. The cause terms $x_{ij}$ are drawn from a mixture of $k_i$ Gaussians distributions. We construct each Gaussian by sampling its mean from Gaussian(0, $r_i$), its standard deviation from Gaussian(0, $s_i$) followed by an absolute value, and its unnormalized mixture weight from Gaussian(0, 1) followed by an absolute value. NCC samples $k_i$ from RandomInteger[1,5] and $r_i, s_i$ from Uniform[0,5]. NCC normalizes the mixture weights to sum to one and $x_{ij} = 0$ to zero mean and unit variance. The noise term $v_{ij}$ and $e_{ij}$ are also sampled from Gaussian distribution and mechanism $f_i$ is a cubic hermite spline which can be referred to [6]. Finally NCC is trained with two embedding layers and two classification layers followed by the softmax in a ternary classification task (causal, anticausal and no causation). Then while testing the model can be used to evaluate on the RoI feature vectors directly. The output $NCC(x \rightarrow y)$ ranges from (0, 1) denotes the relative causality intensity from $x$ inferring $y$.

However since the NCC model just can provide a qualitative prediction and may have huge deviation when applying on real-world feature which may affects the training procedure of our VC R-CNN, in our experiment we just discard few training samples with very strong collider causal structure (i.e., $X \rightarrow Z \leftarrow Y$) by setting a threshold (we set 0.001 in our experiment). Moreover, we use the object-level RoI features extracted by the pretrained Faster R-CNN to pre-calculate the NCC score, which may also lead to a deviation since the pretrained RoI representations may not fully present the objects. From the Table 7 in the main paper we can also observe that NCC refining just brings a little difference to the downstream task performance. The potential reason is that our VC R-CNN can automatically learn the reasonable confounder attention during the large dataset training. We will continue exploring the usage of NCC and other causal discovery method in our future work.

| Index | Input | Operation | Output | Trainable Parameters |
|-------|-------|-----------|--------|---------------------|
| (1)   | -     | RoI feature | $x$ $(1024 \times 1)$ | - |
| (2)   | -     | RoI feature | $y$ $(1024 \times 1)$ | - |

Table 2. The image captioning performances of two models with ablative features (based on vanilla Faster R-CNN feature) on Karpathy split.

C. Network Architecture

Here we introduce the detailed network architectures of all the components of our VC R-CNN in Table 1. Given an image and the feature extraction backbone, any two RoI feature vectors $x$ and $y$ were extracted as in Table 1 (1)(2). Then as the Section 3.2 The Proposed Implementation, we adopted the Scale Dot-Product Attention to refine confounders from the confounder dictionary $Z$ as in Table 1 (3). A linear addition model $f_y(x, z)$ was proposed to combine the effect on $Y$ from both $X$ and confounder $Z$. Finally we made the do calculus by Self Predictor and Context Predictor in Table 1 (6)(7).

D. More Quantitative Results

In the experiment of our main paper, we adopted the bottom-up feature [1] as our base feature. The bottom-up feature pretrained Faster R-CNN on ImageNet [3] and Visual Genome [5] to propose salient object level features with attribute rather than the uniform gird of equally-sized image regions, enable attention to be calculated at the level of semantically meaningful regions and bring a huge improvement in image-and-language tasks.

Here we also concatenated our VC feature onto the vanilla image region representations based on pretrained Faster R-CNN model with ResNet-101 on MS-COCO dataset. Note that for better comparison we utilized the bounding box coordinates of the bottom-up feature to control the number and location of the boxes and then applied new feature in the Image Captioning task. Results are shown in Table 2. We can also observe that concatenating with our VC feature can lead to a huge performance improvement, which demonstrates the stability of our VC feature and effectiveness of the proposed intervention.

E. More Qualitative Results

E.1. Failure Case

Failure in VC R-CNN. As shown in Figure 5, we can see that sometimes our VC R-CNN cannot make quite reasonable refinement for confounder dictionary via the Scaled Dot-Product Attention while predicting $Y$ given $X$ and $Z$, especially when there is no obvious relation between $X$ and $Y$. For example while making the intervention between dog and vase, chair and fork, the model attends to the giraffe and skateboard respectively. To tackle this limitation, the better schedule of confounder exploring, for example choosing approiprte context objects as the confounder dictionary, will be tried in our future work.

Failure in Downstream Tasks. Though we designed the intervention (do-expression) in unsupervised representation learning to prevent the cognition error and help machine learn the common sense, some attention errors still exist in downstream tasks. Here we present two examples in Figure 6. We can observe that in the VQA example (left), the model provides a reasonable but incorrect answer, while in image captioning the generated description does not cover every instance. The possible reason lies in two folds. First, the current detection technique is still limited, for example the Faster R-CNN cannot recognize the kangaroo on the stop sign. Second, we know that our VC R-CNN can find the probable and reasonable confounders from the confounder dictionary according to the given image. However, it may still fail to exploit the exact confounder (e.g., motorcycle in VQA and lamp, chair in Image Captioning) to fully eliminate the correlation bias.
Q: What may cross the road?
GT: Kangaroo
Ours: Motorcycle

Motorcycle: 0.32

GT: A living room with lamps, a couch and a chair.
Ours: A living room with a couch and a table.

Figure 6. The examples of the failure case in downstream tasks.

E.2. Image Captioning

Figure 7 & 8 exhibit visualizations of utilizing our VC feature (right) compared with using Faster R-CNN feature (i.e., bottom-up feature, left) with the classical Up-Down model in image captioning task. The boxes represent the attended regions when generating words with the same color. From the illustration we can observe that with our VC feature, model can generate more fruitful descriptions with more accurate attention. For example, in Figure 8 bottom with our VC feature, model focuses on birds and gives the accurate and fruitful descriptions: “two birds perched” rather than “a bird sitting” generated by the baseline model. Furthermore, we can also see that our VC feature can help to overcome the language bias efficiently. Other than giving the common collections, the model can generate reasonable captions according to the image content. For example in the middle of Figure 8, “cat” appearing with “bed” (“cat+bed”/“cat”=6.7%) is quite more often than “cat” with “blanket” (“cat+blanket”/“cat”=1.4%) in the training text, leading to a “hallucination” to generate “bed” without seeing the bed.

E.3. VQA

We presented the comparison of Faster R-CNN feature (left) and our VC feature (right) in VQA in Figure 9 & 10 based on the Up-Down model. We can see that in VQA task the most serious problem is the incorrect attention even with the correct answer, which means the model actually NOT understand the question and make inference combining the vision and language. As we described in Introduction of the main paper, the dataset co-occurring bias may lead to the incorrect attention. For example in the middle of Figure 9 the model attend to the horse rather than human since horse and person co-occur too many times. Thanks to our VC feature, the attention becomes better and more accurate with alleviating the correlation bias by our proposed intervention.
