(Received 3 June 2013; revised manuscript received 22 August 2013; published 26 September 2013)

We have measured the temperature dependence of the direct band gap $E_g$ in SrTiO$_3$ and BaTiO$_3$ and related materials with quantum-paraelectric and ferroelectric properties using optical spectroscopy. We show that $E_g$ exhibits an anomalous temperature dependence with pronounced changes in the vicinity of the ferroelectric transition that can be accounted for in terms of the Fröhlich electron-phonon interaction with an optical phonon mode, the so-called soft mode. In addition, we demonstrate that these characteristic changes of $E_g$ can be readily detected even in very thin films of SrTiO$_3$ with a strain-induced ferroelectric order. Optical spectroscopy thus can be used as a rather sensitive probe of ferroelectric order in very thin films of these titanates and probably also in subsequent multilayers and devices.

DOI: 10.1103/PhysRevB.88.104110 PACS number(s): 77.80.—e, 63.20.kd, 77.84.Cg, 78.20.—e

I. INTRODUCTION

Ferroelectric (FE) materials have important applications in sensors and electronic devices, for example, in dynamic random access memories.1–3 The growth and characterization in sensors and electronic devices, for example, in dynamic thin films.

or ultraviolet Raman spectroscopy11 have therefore been used

suppressed by quantum lattice fluctuations, a FE order can

quantum-paraelectric material for which the FE order is

hand, in SrTi$_{16}$O$_3$, which in its bulk form is a so-called

arise from poorly screened depolarization fields at surfaces

and interfaces or from strain and defects.1–3 On the other

other, in SrTi$_{16}$O$_3$, which in its bulk form is a so-called

quantum-paraelectric material for which the FE order is

suppressed by quantum lattice fluctuations, a FE order can

be induced in thin films that are strained by lattice matching

to the substrate.4,5 For such thin films and especially for

subsequent complex heterostructures with FE layers, it is

therefore very important to have a readily accessible technique

that enables one to identify the FE order. Direct capacitance

or impedance spectroscopy measurements of the FE order on

such thin films are often complicated and hindered by parasitic

charges forming at interfaces and electrodes that can obscure

the FE contribution.6,7 Dedicated techniques such as piezo-

response force microscopy,8 synchrotron x-ray diffraction,9,10

or ultraviolet Raman spectroscopy11 have therefore been used
to detect the FE order in very thin films. In the following, we

show that standard optical spectroscopy measurements of the

temperature ($T$) dependence of the direct band gap $E_g$

can be used as an alternative and very effective tool to identify

such a FE transition. This is demonstrated for the case of bulk

SrTi$_{16}$O$_3$ and BaTiO$_3$ crystals as well as for strained SrTi$_{16}$O$_3$

thin films.

II. EXPERIMENTAL DETAILS

SrTi$_{16}$O$_3$ (STO) and KTaO$_3$ crystals were purchased

from Crystec12 and a BaTiO$_3$ crystal from SurfaceNet,13

respectively. A polycrystalline CaTiO$_3$ sample was made via

solid-state sintering. A $^{18}$O exchanged SrTi$^{18}$O$_3$ crystal

was prepared as described in Ref. 14. STO thin films on

DyScO$_3$ and (LaAlO$_3$)$_{3}$(SrAlTaO$_6$)$_{0.7}$ (LSAT) substrates

were prepared by pulsed laser deposition with $in$ $situ$ reflection

high-energy electron diffraction growth control. The substrate

temperature was 900 °C, the oxygen pressure $p$(O$_2$) = 0.11 mbar, and we used a 248-nm excimer laser with a fluence of 1.5 J/cm$^2$. Subsequent to the growth, the films were slowly cooled in 1-bar oxygen.

Spectroscopic ellipsometry measurements were performed in the near-infrared to ultraviolet range of 0.5–6.5 eV with a commercial ellipsometer (WOOLLAM VASE$^{15}$) equipped with a UHV cryostat for a temperature range of 4 K < $T$ < 700 K. For the far-infrared (FIR) and mid-infrared measurements, we used a home-built setup as described in Ref. 16. FIR reflectivity measurements were performed with the home-built setup described in Ref. 17. The modeling of the ellipsometry data (surface roughness correction for crystals and substrate correction for thin films) was done with the WOOLLAM VASE software.$^{15}$

III. RESULTS AND DISCUSSION

Figure 1(a) shows the $T$-dependent spectra from 2–6 eV of the real and imaginary parts of the dielectric function $\varepsilon = \varepsilon_1 + i\varepsilon_2$ of bulk STO. They contain four prominent bands centered at 3.7, 4.2, 5.1, and about 6 eV which correspond to direct interband transitions between the O-2$p$ states in the valence band and the Ti-3$d$ states in the conduction band.$^{18,19}$ The indirect band gap at 3.25 eV yields a very weak absorption band that is barely visible in the spectra and therefore does not concern the following discussion of the $T$ dependence of the direct band gap $E_g$ at about 3.7 eV. Figure 1(b) shows the spectra of the second derivative of $\varepsilon_2$ as obtained with a Savitzky-Golay smoothing procedure.$^{20}$ They have been fitted with the second derivative of the function

$$\varepsilon(\omega) = B - Se^{3\pi/2}(\omega - E + i\Gamma)^{1/2}, \tag{1}$$
which describes the response in the vicinity of a direct absorption edge due to the singularity in the joint density of states at a three-dimensional so-called \( M_0 \) critical point.\(^{21,22}\) Further details are given in Appendix A. Here, the parameter \( B \) represents a constant background, \( S \) is the amplitude, \( \Gamma \) the broadening, and \( E \) corresponds to the energy threshold of the associated transition which in this case is the energy of the band gap \( E_g \). The obtained \( T \)-dependence of \( E_g \) and \( \Gamma \) is displayed in Figs. 1(c) and 1(d), respectively. The evolution of \( E_g \) is rather anomalous; it exhibits a sizable increase from \( \sim 3.71 \) eV at 10 K to 3.77 eV at 300 K before it reaches a maximum at \( \sim 3.81 \) eV around 500 K and decreases again toward higher \( T \). We note that this characteristic \( T \)-dependent shift of the interband transition is visible in the bare spectra of Fig. 1(a) using Eq. (1) to the second derivative of the experimental spectra of \( \varepsilon_{\text{STO}} \). (b) Corresponding second derivative spectra of \( \varepsilon \), \( T \)-dependence of \( E_g \) and \( \Gamma \) and the broadening, and \( E \) and the broadening, and \( E_g / \Gamma_1 \) broadening.

The magnitude of \( E_g \) in semiconductors and insulators is well known to undergo sizable changes with \( T \), usually to lower energy, as in Si, Ge, or GaAs,\(^{24,25}\) but in some cases as in PbS also to higher energy.\(^{26}\) Part of this \( T \)-dependence is accounted for by the thermal expansion of the lattice, but a sizable contribution can also arise from the electron-phonon interaction.\(^{27,28}\) The latter is caused by the deformation of the electronic potentials due to the dynamic atomic displacements. Its sign is determined by the lattice structure and the electronic states forming the valence and conduction bands. Its magnitude depends on the amplitude of the atomic displacement \( u \), which in the harmonic approximation is related to the effective mass of the atoms \( \mu \), the eigenfrequency of the phonon mode \( \omega \), and the Bose-Einstein factor \( n_B = \left( e^{\hbar \omega/k_BT} - 1 \right)^{-1} \), according to \( \langle u^2 \rangle = \frac{\hbar^2 \mu}{2m_B(1 + 2n_B)} \) (solid line) using Eq. (1) to the second derivative of the experimental data (open symbols) at \( T = 8 \) K.

\[
\Delta E_g = -A\left( e^{-\frac{1}{k_BT}} - e^{-\frac{\omega}{k_BT}} \right)(1 + 2n_B),
\]

where \( \varepsilon_{\infty} \) and \( \varepsilon_0 \) are the dielectric constants at energies well above and below the phonon range, respectively, and \( A \) is a \( T \)-independent prefactor that depends on material parameters such as effective mass and lattice constant. It is important to notice that at \( k_BT \ll \hbar \omega \), where \( n_B \) is nearly constant, the \( T \)-dependence of \( \Delta E_g \) is determined by that of \( \varepsilon_0 \).

In the following, we provide evidence that in STO and related titanates this Fröhlich interaction governs the \( T \)-dependence of \( E_g \) below about 250 K. In STO, the thermal expansion of the lattice has a regular \( T \)-dependence\(^{32,33}\) and thus should contribute to a decrease of \( E_g \) as the lattice expands with increasing \( T \). This assumption is confirmed by band-structure calculations which predict that \( E_g \) increases with pressure (or decreasing lattice constant).\(^{34}\) The structural phase transitions at 105 K from a cubic to a tetragonal state and around 65 K toward an orthorhombic phase also do not have any noticeable effect on \( E_g \). This suggests that the unusual \( T \)-dependence of \( E_g \) in STO is caused by the electron-phonon interaction. STO is indeed well known for its anomalous lattice dynamical properties. It is a so-called quantum-parametric material with an incipient FE state below about 35 K (Ref. 35) that is suppressed by the quantum lattice fluctuations.\(^{36}\) This anomalous behavior is closely related to the softening of a transverse optical (TO) phonon which involves a polar displacement of the Ti ion away from the central position of the octahedron formed by the neighboring oxygen ions. The eigenfrequency of this so-called "soft mode" \( \omega_{\text{TO}} \) decreases from about 95 cm\(^{-1}\) at 300 K to about 15 cm\(^{-1}\) at low \( T \).\(^{37}\) We have also measured the \( T \)-dependence of \( \omega_{\text{TO}} \) with far-infrared ellipsometry as described in Appendix B and shown in Fig. 4(a). According to the Lyddane-Sachs-Teller relation \( \frac{\omega_{\text{TO}}}{\omega_\text{LO}} = C \frac{\omega_\text{LO}}{\omega_{\text{TO}}} \) this soft TO mode gives rise to a strong increase of \( \varepsilon_0 = 390 \) at 300 K to \( \varepsilon_0 = 14,000 \) at low \( T \).\(^{38,39}\) The open squares in Fig. 1(c) show that this divergence of \( \varepsilon_0 \) toward low \( T \) and the subsequent increase of the Fröhlich interaction according to Eq. (2) account well for the renormalization of \( E_g \) below about 250 K. The fit to the \( E_g \) data yields a vertical offset of \( E_g(T = 0 \text{ K}) = 4.15 \pm 0.02 \) eV and a prefactor of \( A = 2.26 \pm 0.12 \) eV. The prefactor \( C = 2.52 \pm 0.12 \) in the Lyddane-Sachs-Teller relation, which accounts for the \( T \)-independent contribution of the two other IR-active phonon modes at 175 and 540 cm\(^{-1}\), and the values of \( \varepsilon_{\infty} = 5.1 \) and the eigenfrequency of the LO mode \( \omega_{\text{LO}} = 788 \) cm\(^{-1}\), have been obtained from the ellipsometry data as is described in Appendixes C and D, respectively. The latter have only a very small contribution to the softening of the transverse optical (TO) phonon which involves a polar displacement of the Ti ion away from the central position of the octahedron formed by the neighboring oxygen ions. The eigenfrequency of this so-called "soft mode" \( \omega_{\text{TO}} \) decreases from about 95 cm\(^{-1}\) at 300 K to about 15 cm\(^{-1}\) at low \( T \).\(^{37}\) We have also measured the \( T \)-dependence of \( \omega_{\text{TO}} \) with far-infrared ellipsometry as described in Appendix B and shown in Fig. 4(a). According to the Lyddane-Sachs-Teller relation \( \frac{\omega_{\text{TO}}}{\omega_\text{LO}} = C \frac{\omega_\text{LO}}{\omega_{\text{TO}}} \) this soft TO mode gives rise to a strong increase of \( \varepsilon_0 = 390 \) at 300 K to \( \varepsilon_0 = 14,000 \) at low \( T \).\(^{38,39}\) The open squares in Fig. 1(c) show that this divergence of \( \varepsilon_0 \) toward low \( T \) and the subsequent increase of the Fröhlich interaction according to Eq. (2) account well for the renormalization of \( E_g \) below about 250 K. The fit to the \( E_g \) data yields a vertical offset of \( E_g(T = 0 \text{ K}) = 4.15 \pm 0.02 \) eV and a prefactor of \( A = 2.26 \pm 0.12 \) eV. The prefactor \( C = 2.52 \pm 0.12 \) in the Lyddane-Sachs-Teller relation, which accounts for the \( T \)-independent contribution of the two other IR-active phonon modes at 175 and 540 cm\(^{-1}\), and the values of \( \varepsilon_{\infty} = 5.1 \) and the eigenfrequency of the LO mode \( \omega_{\text{LO}} = 788 \) cm\(^{-1}\), have been obtained from the ellipsometry data as is described in Appendixes C and D, respectively. The latter have only a very
respectively. The value of $\omega$ calculations for FE BaTiO$_3$ with of STO (stars) shown for comparison. (d) Corresponding data and $T$ the Fröhlich interaction as obtained with Eq. (2). (c) Corresponding (a) KTaO$_3$ and (b) CaTiO$_3$. Open squares show the contribution of $E_g$ towards low $T$ with a FE transition at $T_{\text{Curie}} = 26$ K as marked by the arrow. Inset: Magnification of the low-$T$ regime with the rescaled data of STO (stars) shown for comparison. (d) Corresponding data and calculations for FE BaTiO$_3$ with $T_{\text{Curie}} = 405$ K.

weak $T$ dependence as shown (see Figs. 5 and 6) that does not strongly influence our estimates for the shift of $E_g$ due to the Fröhlich interaction.

Figure 2(a) shows the $T$ dependence of $E_g$ in KTaO$_3$ which is also a quantum-paraelectric material with a soft TO phonon mode. The corresponding spectra of the dielectric function and of its second derivative are shown in Appendix E. Similar to STO, the value of $E_g$, as derived from the optical spectra, exhibits a strong increase with $T$ up to about 300 K. The open squares show that the Fröhlich interaction accounts once more well for the $T$-dependent renormalization of $E_g$ below 250 K. The determination of the $T$ dependence of $\omega_{\text{TO}}$ and of $\epsilon_\infty$ is once more described in the Appendixes B and D, respectively. The value of $\omega_{\text{TO}} = 833$ cm$^{-1}$ has been taken from Ref. 41. The fit using Eq. (2) yields a vertical offset of $E_g(T = 0 \text{ K}) = 4.87 \pm 0.01$ eV, $A = 2.24 \pm 0.06$ eV, and $C = 2.92 \pm 0.07$. The corresponding data and fits for CaTiO$_3$ with $C = 1.89 \pm 0.08$, $E_g(T = 0 \text{ K}) = 4.35 \pm 0.03$ eV, and $A = 3.30 \pm 0.15$ eV are displayed in Fig. 2(b). They confirm that the soft-mode behavior and the resulting divergence of $\epsilon_0$ towards low $T$ are governing the renormalization of $E_g$. This confirms the important role of the Fröhlich electron-phonon interaction in the anomalous $T$ dependence of $E_g$ in these quantum-paraelectric materials.

In return, the characteristic $T$ dependence of $E_g$ can be used to monitor the soft-mode behavior and to identify a possible FE transition in these materials. We demonstrate this first for the case of oxygen isotope substituted SrTi$_{18}$O$_3$ for which a weak FE order that is stabilized by the reduction of the lattice quantum fluctuations develops below $T_{\text{Curie}} \approx 26$ K. The measured ellipsometry spectra and their second derivatives are shown in Figs. 8(a) and 8(b) in Appendix E. Figure 2(c) shows that the $T$ dependence of $E_g$ exhibits indeed a weak, yet clearly noticeable, anomaly at $T_{\text{Curie}} \approx 26$ K. This anomaly is marked by an arrow and is more clearly shown in the inset which compares the low-$T$ behavior of $E_g$ in SrTi$_{18}$O$_3$ (full circles) with the one of the rescaled $E_g$ (by a factor of 1.0015) of SrTi$_{18}$O$_3$ (stars). Shown by the open squares is the contribution of the Fröhlich interaction as obtained using Eq. (2) with $C = 1.88 \pm 0.05$ and $\omega_{\text{LO}}(765$ cm$^{-1}$, $\epsilon_\infty = 5.1$, and the $T$ dependence of $\omega_{\text{TO}}$ as measured with infrared spectroscopy (see Appendixes B–D). The latter exhibits an anomalous hardening below $T_{\text{Curie}}$ as is shown in Fig. 4(c) in Appendix B. The fit yields $E_g(T = 0 \text{ K}) = 4.34 \pm 0.02$ eV and $A = 3.16 \pm 0.10$ eV and reproduces the $T$ dependence of $E_g$ and also the anomaly around $T_{\text{Curie}} \approx 26$ K rather well.

It has been predicted that the static displacement $u$ that occurs below the FE transition will also contribute to the hardening of $E_g$. It reduces the symmetry of the lattice and thereby can introduce a mixing of the oxygen and titanium related bands that leads to a repulsion of the valence and conduction bands which increases $E_g$. Nevertheless, the good agreement in Fig. 2(c) between the measured $E_g$ values and the estimated contribution of the Fröhlich interaction suggests that the latter accounts for a sizable and possibly even the major part of the hardening of $E_g$ in the FE state.

In Fig. 2(d), we show that similar arguments likely even apply for the case of BaTiO$_3$ for which the formation of a FE state with a large polarization below $T_{\text{Curie}} = 405$ K gives rise to a much stronger anomaly in the $T$ dependence of $E_g$ than in SrTi$_{18}$O$_3$. Figure 2(d) shows that whereas $E_g$ is only weakly $T$ dependent in the paraelectric state at $T > T_{\text{Curie}}$, right below $T_{\text{Curie}}$ it exhibits a steep increase that is about 50 times stronger than the one in SrTi$_{18}$O$_3$. In BaTiO$_3$ the situation is somewhat complicated by the fact that there exist two soft TO modes that both contribute to the divergence of $\epsilon_0$ at $T_{\text{Curie}}$. The additional low-frequency mode (the so-called central mode) accounts here for the order-disorder component of the FE transition which apparently is of a mixed character. Accordingly, we explicitly included the $T$ dependence of both soft TO modes in the Lyddane-Sachs-Teller relation using $\omega_{\text{TO}}$ as reported in Refs. 44–46. The values of $C = 4.78 \pm 0.20$, $\omega_{\text{LO}}(300 \text{ K}) = 716$ cm$^{-1}$, and $\epsilon_\infty = 5.3$ were once more obtained from our IR ellipsometry data as described in Appendixes C and D, respectively. The open squares in Fig. 2(d) show that the large anomaly of $E_g$ in BaTiO$_3$ can be reasonably well reproduced in terms of the Fröhlich interaction with the fit parameters $E_g(T = 0 \text{ K}) = 3.72 \pm 0.01$ eV and $A = 0.63 \pm 0.01$ eV that are not too far from the ones in STO. We notice that the agreement could be further improved by including additional contributions from the coupling to the other phonon modes (which do not soften toward $T_{\text{Curie}}$) and the thermal lattice expansion. These can become rather sizable in the vicinity of $T_{\text{Curie}} = 405$ K and may, for example, account for the rather weak $T$ dependence of $E_g$ in the paraelectric state.

Last but not least, we show in Fig. 3 that the anomaly in the $T$ dependence of $E_g$ can be used to identify the FE order in STO thin films. It is well known that a FE order can be induced in STO thin films that are grown on substrates which introduce a strong tensile strain. For orthorhombic, (110)-oriented DyScO$_3$ substrates, the average mismatch with respect to the lattice parameters of bulk SrTiO$_3$ is about $+1\%$.
For fully lattice-matched STO, this amounts to a sizable tensile stress of ∼1 GPa and an induced FE transition at \( T_{\text{Curie}} \sim 300 \) K. This FE state has been previously identified with piezo-force scanning microscopy,\(^8\) synchrotron x-ray diffraction,\(^9\) and more recently with THz and FIR spectroscopy studies of the \( T \) dependence of the soft TO mode as shown in Figs. 3(c) and 3(d). For the thinner films, these far-infrared data are increasingly difficult to interpret since the signal from the STO phonons becomes much weaker than the one from the DyScO\(_3\) substrate (which also exhibits a considerable penetration depth of the light which is much shorter in the VIS-UV range (\( >1000 \) nm)). Finally, Fig. 3(a) also shows our optical data of a STO thin film grown on a LSAT substrate which exerts a weak compressive strain that does not induce a FE transition.\(^3\) Here, the \( T \) dependence of \( E_g \) exhibits indeed no sign of an anomaly and is similar to the one in bulk STO.

IV. CONCLUSIONS

In summary, we have shown that the anomalous \( T \)-dependent shift of the direct band gap of STO is strongly affected and likely even dominated by the Fröhlich electron-phonon interaction with the so-called soft mode that is at the heart of its quantum-paraelectric properties. We have also demonstrated that the optical band-gap measurements can therefore be used as a very sensitive and efficient tool to search for a ferroelectric order in related bulk and thin-film materials. In particular, we have shown that the strain-induced ferroelectric order in STO films on a DyScO\(_3\) substrate can be readily detected even in films that are only 5 nm thick. This well-established optical technique, which is accessible in many laboratories, could be rather useful to search for ferroelectric transitions in other bulk and thin-film materials, in particular, in complex heterostructures and devices with buried ferroelectric layers. It will also be interesting to study relaxor ferroelectric, improper ferroelectric, or even multiferroic materials to investigate whether they exhibit a similar relationship between the enhancement of the dielectric constant and the renormalization of the direct band gap due to the Fröhlich-type electron-phonon interaction.

This work has been supported by the Schweizer Nationalfonds (SNF) Grant No. 200020-140225 and the project “CEITEC-Central European Institute of Technology” (Project No. CZ.1.05/1.1.00/02.0068). We thank K. Conder for his help in preparing the isotope exchanged SrTi\(_{18}\)O\(_3\) crystal and B. Doggett for his contribution to the PLD thin-film growth. We acknowledge stimulating discussions with M. Cardona and E. Kotomin.

APPENDIX A: FITTING OF THE DIRECT INTERBAND TRANSITION

The numerical derivatives of the real and imaginary parts \( \varepsilon_1 \) and \( \varepsilon_2 \) of the measured dielectric function have been independently calculated using an implementation of the Savitzky-Golay smoothing algorithm in PYTHON.\(^{48}\) The code yields also the \( n \)th numerical derivative of the input data with respect to the input \( x \) value, i.e., the energy in our case. Care has been taken that no artificial features are introduced by the smoothing procedure. The real and imaginary parts \( \frac{\partial \varepsilon_1}{\partial E} \) and \( \frac{\partial \varepsilon_2}{\partial E} \) have been fitted simultaneously in the vicinity of the \( M_0 \) critical point using the second derivative of Eq. (1). After the fitting, the parameters for the energy \( E \), the prefactor \( S \), and the broadening \( \Gamma \) for the transition have been obtained as exemplary shown in Fig. 1 for SrTi\(_3\)O\(_4\).

It is important to note that the maxima of the derivative spectra do not necessarily coincide with the extracted energies of the interband transitions. The phase factor \( p = \frac{\pi}{2} \) in the exponent results in a mixing of real and imaginary parts of the dielectric function close to the resonance. This can lead to

![Graphical representation of data](image-url)
APPENDIX B: T DEPENDENCE OF THE SOFT TO MODE

The eigenfrequency of the transverse optical branch of the soft mode $\omega_{TO}$ of SrTiO$_3$ is known to exhibit a strong T dependence that originates from the quantum-paraelectric behavior. Figure 4(a) shows the result of a Lorentz oscillator fit of the soft mode in the far-infrared ellipsometry spectra which has been performed over a broad temperature range. Figure 4(b) shows that a similar softening of $\omega_{TO}$ is observed in the incipient-ferroelectric perovskite KTaO$_3$ and also in CaTiO$_3$.

In the ferroelectric state, the soft mode is expected to harden again. Such a behavior is indeed observed in the ferroelectric state of SrTi$_{18}$O$_3$ at $T \leq T_{Curie} = 26$ K. Figure 4(c) displays the T dependence of $\omega_{TO}$ which has been deduced from the peak position of the soft mode in the dielectric function. The latter has been obtained from far-infrared reflectivity data of SrTi$_{18}$O$_3$ by using a Kramers-Kronig transformation. It shows that the soft-mode eigenfrequency $\omega_{TO}$ exhibits a weak, yet clear minimum at $T_{Curie} = 26$ K as marked by the arrow in Fig. 4(c). In the ferroelectric phase between 30 and 5 K there is indeed a characteristic hardening of $\omega_{TO}$ by $\sim 5$ cm$^{-1}$. A similar value has been previously obtained from Raman measurements on SrTi$_{18}$O$_3$. The $T$ dependence of the soft mode in BaTiO$_3$ has been extracted from the literature data for the hyper-Raman scattering, the far-infrared spectroscopy in Ref. 44 for $T < T_{Curie}$, and the lower-energy phonon branch as observed in the infrared spectroscopy for $T > T_{Curie}$ in Ref. 45. The estimated phase transition temperature of $T_{Curie} = 405$ K of these assembled experimental results agrees well with $T_{Curie}$ of the sample that has been investigated in this work.

APPENDIX C: DETERMINATION OF $\omega_{LO}$

In an insulator such as SrTiO$_3$, the eigenfrequency of a longitudinal optical phonon mode $\omega_{LO}$ can be accurately determined from the zero crossing of the real part of the dielectric function $\varepsilon_1$ or likewise from a maximum in the
so-called loss function

\[ -\text{Im} \left( \frac{1}{\varepsilon} \right) = \frac{e_2}{\varepsilon_1^2 + e_2^2}. \]  

Figure 5(a) shows for the case of the room-temperature spectra of SrTiO$_3$, BaTiO$_3$, CaTiO$_3$, and SrTi$_{18}$O$_3$ that this procedure can be used to accurately determine the value of $\omega_{LO}$ (as indicated by the arrows). For these perovskites, a large TO–LO splitting is observed due to the high ionicity of these materials. Hence, for the soft mode $\omega_{LO}$ is located in the mid-infrared range at 716, 808, 788, and 765 cm$^{-1}$ for BaTiO$_3$, CaTiO$_3$, SrTiO$_3$, and SrTi$_{18}$O$_3$, respectively. For KTaO$_3$ we used the value of $\omega_{LO} = 833$ cm$^{-1}$ that is reported in Ref. 41.

In these insulating titanates, the value of $\omega_{LO}$ of the soft mode is hardly temperature dependent. This is demonstrated in Fig. 5(b) for the case of SrTiO$_3$ which shows that the position of the peak in the loss function, as derived from our mid-infrared ellipsometry measurements, hardly changes with temperature. This has been also previously shown by Servoin and Gervais in Ref. 38.

APPENDIX D: DETERMINATION OF $\varepsilon_0$ AND $\varepsilon_\infty$

We have derived $\varepsilon_0$ from the Lyddane-Sachs-Teller relation $\frac{e_0}{\varepsilon_\infty} = C \frac{\omega_{TO}}{\omega_{LO}}$, using the values of $\omega_{TO}$, $\omega_{LO}$, $\varepsilon_\infty$, and $C$ as determined from the far- to near-infrared ellipsometry spectra. We have already shown how $\omega_{TO}$ and $\omega_{LO}$ have been obtained from these optical spectra. In the following, we discuss how the values of $C$ and $\varepsilon_\infty$ have been obtained from these ellipsometry data. The prefactor $C$ accounts for the $T$-independent contribution due to the other infrared-active phonon modes. The spectral weight of these modes has been obtained from the far-infrared ellipsometry data by fitting with Lorentzian functions (not shown here). The value of $\varepsilon_\infty$ has been deduced from the near-infrared ellipsometry data. Figure 6 shows that, for this energy range, which is well above the phonons and well below the interband transitions (or the gap energy), the real part of the dielectric function is only weakly $T$ dependent and exhibits a very moderate and continuous dispersion. For our calculations we used the value of $\varepsilon_\infty$ at $E = 0.9$ eV at 300 K. We note that the very weak $T$ variation of $\varepsilon_\infty$ of less than a percent does not strongly influence our estimate of the band-gap shift due to the Fröhlich interaction. According to Eq. (1), the Fröhlich interaction is governed by the very large $T$-dependent changes of $\varepsilon_0$ which arise from the soft-mode behavior.

APPENDIX E: NIR-UV ELLIPSOLOMTRY SPECTRA OF KTaO$_3$, CaTiO$_3$, SrTi$_{18}$O$_3$, AND BaTiO$_3$

In Fig. 7, we show typical ellipsometry spectra for the incipient ferroelectric material KTaO$_3$ and for CaTiO$_3$ in terms of the real and imaginary parts of the dielectric function $\varepsilon = \varepsilon_1 + i\varepsilon_2$ together with the corresponding second derivative spectra of the imaginary part $\frac{d^2 \varepsilon_2}{d\varepsilon_2}$. Corresponding data for the ferroelectric materials SrTi$_{18}$O$_3$ and BaTiO$_3$ are shown in Fig. 8. All presented spectra have been corrected for surface roughness effects using the WOOLLAM VASE software. The surface roughness has been found to be on the order of $\leq 4$ nm for all investigated samples and it showed only a weak variation with temperature during a measurement cycle. Only during the measurements at $T > 550$ K we have sometimes observed a decrease in the roughness that occurred during or after the measurements.
