(Received on January 4, 2008; accepted on April 30, 2008)

The recrystallization and grain growth characteristics of pre-deformed Fe–1.9vol%Bi alloy specimens in the two-phase region of αFe and liquid Bi were investigated by microstructural observation. Precipitate-free zones (PFZs) were mainly formed in the vicinity outside of the curved grain boundaries. Furthermore, large Bi particles were also observed on the grain boundaries of the matrix along the PFZs. These results suggest that the intragranular liquid Bi particles were trapped and dragged by grain boundaries. The grain growth of the matrix phase was extremely retarded by the effect of this dragging.

KEY WORDS: liquid particle; dragging effect; Ostwald ripening; interfacial energy; grain growth; diffusion.

1. Introduction

It is generally known that the high-wettable liquid phase in polycrystalline materials causing the formation of film-like structure along matrix grain boundaries results in liquid metal embrittlement. However, it has recently been reported by Koike et al.1) that Al–Bi alloys which include a small amount of liquid Bi particles show a superplasticity of more than 200%. Furthermore, Kainuma et al.2) reported that the grain growth in the Al–Bi alloys was retarded by the dragging of liquid Bi particles, that precipitate-free zones (PFZs) were formed in the vicinity outside of the curved grain boundaries and that larger particles grew on the grain boundaries along the PFZs. The same kind of phenomenon has been reported in several other alloy systems. For instance, Ashby and Centamore3) observed that the dispersing liquid oxide particles in the Cu matrix phase moved together with the grain boundaries. They concluded that the average dragging distance is dependent on the viscosity of the particles. Koch et al.4) and Ziling et al.5) also reported a similar phenomenon on (Cr, Fe)23C6-type carbides in an austenite stainless steel and on Al2O3 particles in a Cu–Al alloy, respectively. On the other hand, Geguzin and Krivoglaz6) and Gottstein and Shvindlerman7) theoretically analyzed the dragging phenomenon as the migration of a spherical particle receiving an external force. A Monte Carlo simulation of the grain growth behavior in polycrystalline material with highly mobile particles examined by Hassold and Srolovitz8) showed that the grain growth of the matrix phase can be retarded by the existence of mobile particles.

Practical applications of metallic alloys with a dispersed phase with a low melting point have been conducted in the field of machinable materials. For instance, Pb has long been used as free-cutting material not only in steels, but also in aluminum- and copper-based bearing alloys. However, it has become necessary to replace Pb with other material, because of environmental problems with the toxicity of Pb. Therefore, inclusions such as manganese sulfide, graphite, and calcium oxide have been used, and the addition of Bi in steel is also expected to be a promising candidate of Pb-free machinable steel, the melting point of Bi (545 K) being comparable to that of Pb.

Figure 1 shows the Fe–Bi binary phase diagram,9) which indicates that pure Bi particles are dispersed in a pure Fe matrix through a monotectic reaction. In the present work, the effects of liquid Bi particles on the recrystallization and grain growth characteristics of αFe in the Fe–Bi alloy were investigated.

![Fig. 1. Fe–Bi binary phase diagram.](Image)
2. Experimental Procedure

A Fe–1.9 vol% Bi alloy and a pure Fe were prepared as columnar ingots with a diameter of 12 mm by induction melting in an argon atmosphere. Each ingot was cold-rolled into a sheet with a thickness of 2.4 mm by 80% reduction. The specimens cut from the rolled sheet were isothermally annealed at 1173 K, which is higher than the melting temperature of 545 K for Bi, for recrystallization and grain growth, and then quenched in ice water. The microstructure of the annealed specimens was observed by optical microscopy (OM) and scanning electron microscopy (SEM). An etchant consisting of 50 vol% of ethanol and 50 vol% of nitric acid was used for the OM observation. The mean grain radius of the matrix phase was determined by quantitative microstructure analysis, and the volume fraction and the mean radius of the liquid Bi particles were estimated with an image analysis software (Win Roof). The recrystallization was examined by the micro-Vickers hardness (MVH) test and the microstructural observation. The chemical compositions of the matrix phase and the liquid particle were determined by electron probe microanalysis (EPMA), the calibration being performed by ZAF correction of the data of more than 5 points for each phase.

3. Results

3.1. Recrystallization in Fe–Bi Alloy

Since the grain growth continuously proceeds after recrystallization during isothermal annealing at 1173 K after cold-rolling, the end of recrystallization was estimated by hardness measurements.

Figure 2 shows the value of MVH versus the annealing time \( t \) for the pre-deformed Fe–1.9 vol% Bi alloy at 1173 K. In the case of a pre-deformed pure Fe, the MVH, which shows HV=185 in the as-rolled specimen, drastically decreases to HV=95 due to annealing for 30 s and maintains a MHV of around HV=100 at all the annealing times over 30 s. On the other hand, the MVH of the pre-deformed Fe–1.9 vol% Bi alloy, which is HV=170 in the as-rolled specimen, gradually decreases until 120 s and becomes steady at about HV=85 after 120 s.

![Fig. 2. Vickers hardness of pre-deformed Fe–1.9vol% Bi alloy annealed at 1173 K.](image)

3.2. Grain Growth in Fe–Bi Alloy

The stability of crystal grains is known to be related to the balance of grain boundary energies at triple junctions. For example, in the case of 2-dimensional (2-D) polycrystalline materials, hexagonal grains with an equilibrium angle of 120° at the boundary junction are most stable, and the total number of boundaries around a grain with more and less than six sides may grow and shrink, respectively. However, it is usually difficult to directly confirm such motion of grain boundaries. In the present study, the trajectory
of the grain boundary migration was observed by the distribution of fine liquid particles dispersed in the matrix grain.

Figures 4(a) and 4(b) show an OM micrograph and a schematic illustration of the Fe–1.9vol%Bi alloy annealed at 1 173 K for 3 weeks. The broken lines represent the previous location of the grain boundary. PFZs are observed in the vicinity outside of curvature of the grain boundaries, and some large particles are located only on the grain boundaries along the PFZs. These results imply that fine intragranular Bi particles are swept out by grain boundaries and that the swept particles preferentially grow due to Ostwald ripening on the grain boundaries.

Figure 5 shows the mean radius versus the annealing time for the intra- and inter-granular liquid Bi particles at 1 173 K. The ripening rate of the grain boundary particles is faster than that of intragranular ones. This suggests that the ripening mechanism of the grain boundary particles is basically different from that of the intragranular ones. The ripening mechanism of the liquid Bi particles will be discussed later on.

Annealing time dependence of the mean grain radius for the Fe–1.9vol%Bi alloy annealed at 1 173 K is shown together with that for the pure Fe in Fig. 6. It is apparent that the grain growth in the Fe–Bi alloy containing the liquid Bi particles is much more sluggish than that in the pure Fe. These results show that the dragging of the liquid Bi particles plays an important role in the grain growth of the matrix phase.

4. Discussion

4.1. Effects of Liquid Bi Particles on Recrystallization

Second-phase particles sometimes act as pinning sites for the interface migration of the recrystallizing grains. When the second-phase particles are randomly distributed in the deformed matrix, the pinning force \( \Delta G_{\text{pin}} \) on the unit area of grain boundaries is expressed by

\[
\Delta G_{\text{pin}} = \frac{3 \cdot f \cdot \sigma}{2 \cdot r}
\]

where \( f \) and \( r \) are the volume fraction and the mean particle radius of dispersing particles, respectively, and \( \sigma \) is the grain boundary energy of the matrix phase. For the present Fe–1.9vol%Bi alloy annealed at 1 173 K for 2 min, values of \( f=0.019 \) and \( r=0.11 \mu m \) are obtained from the experimental result. On the other hand, \( \sigma=0.80 \text{ J} \cdot \text{m}^{-2} \) is reported as the grain boundary energy for Fe. Using these parameters, the pinning force is evaluated as

\[
\Delta G_{\text{pin}} = 2 \times 10^7 \text{ J} \cdot \text{m}^{-3} = 0.2 \text{ MPa}
\]

Since the driving force for recrystallization is usually on the order of about 1–10 MPa, the recrystallization process of the matrix is expected to be hardly affected by the liquid Bi particles. This result can be confirmed by the fact that the distribution of the fine liquid Bi particles before the recrystallization seems to be inherited by the recrystallized microstructure, as shown in Fig. 3.
4.2. Ostwald Ripening of Liquid Bi Particles

4.2.1. Intragranular Bi Particles

It is well known that the driving force for the ripening of particles is the consumption of interfacial energy between the matrix and the particles. If the ripening of particles is controlled by volume diffusion of solute atoms in the matrix phase, the ripening rate of spherical particles is expressed by

\[ \bar{r}^3 - \bar{r}_0^3 = k_3 \cdot t \] ..........................(2)

where \( t \) is the annealing time, \( \bar{r} \) and \( \bar{r}_0 \) are the mean particle radii at \( t \) and \( t=0 \), respectively. \( k_3 \) is the rate constant given by \( k_3 = \frac{8 D_x \cdot \sigma_{gb} \cdot N_x \cdot V_b}{9RT} \) ...........................(3)

where \( D_x \) is the impurity diffusion coefficient of the solute in the matrix phase, \( \sigma_{gb} \) is the interfacial energy between the matrix and particle phases, \( N_x \) is the solubility of the solute in the matrix phase measured in atomic fraction, \( V_b \) is the molar volume of the particle, \( R \) is the gas constant and \( T \) is the absolute temperature. The annealing time dependence of the cube of the mean particle radius at 1 173 K is shown in Fig. 7. As can be seen, the cube of the mean particle radius linearly increases with increasing annealing time. The experimental rate-constant for the ripening of the intragranular particles can be estimated to be \( k_{3}\ exp = \frac{2.2 \times 10^{-26}}{10^3} \) m\(^3\) s\(^{-1}\) from the slope of Fig. 7. In order to confirm the reliability of this mechanism in the present case, the theoretical rate-constant was calculated by Eq. (3) as \( k_{3}\ \ exp = 5.5 \times 10^{-26} \) m\(^3\) s\(^{-1}\) using the parameters shown in Appendix A1. The theoretical value is on the same order as the experimental one, and it can be considered that the ripening of the intragranular particles in the Fe–Bi alloy is controlled by the impurity volume diffusion of Bi in the matrix phase.

4.2.2. Intergranular Bi Particles

When the ripening of the intergranular Bi particles is controlled by grain boundary diffusion, the ripening rate is given by

\[ \bar{r}^4 - \bar{r}_0^4 = k_4 \cdot t \] ..........................(4)

where \( k_4 \) is the rate constant shown by \( k_4 = \frac{9w \cdot D_{gb} \cdot \sigma_{gb} \cdot N_x(gb) \cdot V_m}{32A \cdot B \cdot RT} \) ..........................(5)

Here, \( w \) is the grain boundary thickness, \( D_{gb} \) is the grain boundary diffusion coefficient and \( N_x(gb) \) is the concentration of the solute at the grain boundary. \( A \) and \( B \) are the constants written as

\[ A = \frac{2}{3} + \frac{\sigma_b}{2\sigma} + \frac{1}{3} \left( \frac{\sigma_b}{2\sigma} \right)^3 \] ..........................(6)

and

\[ B = \frac{1}{2} \ln \left( \frac{1}{f_b} \right) \] ..........................(7)

where \( \sigma_b \) is the grain boundary energy of the matrix phase and \( f_b \) is the fraction of the grain boundary covered by the second-phase particles. The grain boundary diffusion is usually given with the segregation coefficient \( K_{gb} = N_x(gb)/N_x \). Using a form of \( K_{gb} \cdot w \cdot D_{gb} \) in the diffusion database, Eq. (5) can be rewritten as

\[ k_4 = \frac{9K_{gb} \cdot w \cdot D_{gb} \cdot \sigma_{gb} \cdot N_x \cdot V_m}{32A \cdot B \cdot RT} \] ..........................(5')

In order to examine the validity of Eqs. (4)–(7), the fourth power of the mean radius \( \bar{r} \) of the intergranular Bi particles is plotted against the annealing time \( t \) in Fig. 8(a). As shown in Fig. 8(a), it was found that the linear relationship between \( \bar{r}^4 \) and \( t \) is satisfied at longer annealing times. Fig.
Appendix A2. The calculated rate constant was experimentally estimated to be $k_4 \text{exp} = 6.5 \times 10^{-31} \text{m}^4 \text{s}^{-1}$ from the slope of Fig. 8, which is compared with the theoretical rate constant calculated from Eqs. (5)–(7) as $k_4 ^{\text{th}} = 3.2 \times 10^{-31} \text{m}^4 \text{s}^{-1}$ using the parameters described in Appendix A2. The calculated rate constant $k_4 ^{\text{th}}$ is of the same order as that of the observed $k_4 ^{\text{exp}}$. Therefore, it can be considered that the ripening of the intergranular Bi particles at longer annealing times is basically controlled by grain boundary diffusion of the solute.

4.3. Growth Rate of the Matrix Phase in Fe–Bi Alloy

Interaction between the grain growth of the matrix and the second-phase particles is generally expressed by\textsuperscript{16}

$$
\overline{R} = \beta \cdot \frac{P}{f} 
$$

Here, $\overline{R}$ is the mean grain radius of the matrix, and $f$ and $P$ are the mean radius and the volume fraction of the second-phase particle, respectively. $\beta$ and $m$ are the constants, these values of $\beta$ and $m$ having been proposed by many researchers.\textsuperscript{17,18} In the case of the original Zener relation,\textsuperscript{16} the distribution of particles is assumed to be random and the correlation is given by $\beta = 4/3$ and $m = 1$. If all the particles are located on grain boundaries, the constants are theoretically given by $\beta = 2$ and $m = 1/2$. Also, 2-D simulation of this case was conducted by Doherty et al.,\textsuperscript{19} who reported that the constants are given by $\beta = 1.7$ and $m = 1/2$. In the Fe–Bi alloy annealed for long times, the grain growth of the matrix was extremely retarded by the dispersion of the liquid Bi particles. This means that the ripening of the intergranular Bi particles is important as a retardation mechanism of grain boundary migration. The relationship between the matrix and the intergranular particles is therefore plotted in Fig. 10. In this figure, the abscissa represents the division of the mean radius $\bar{R}_b$ of the intergranular particles...
by the square root of the volume fraction of the intergranular particles. As shown in Fig. 10, the gradient of the Zener relation was divided into two regions of unsteady and steady state. This result was consistent with the experimental data for the ripening of the intergranular particles shown in Fig. 8.

If the ripening rate for the intergranular particles and the Zener relation are estimated as $R^4 - R_0^4 = k^4_{\text{Matrix}} \cdot t$ and $R = R_{\text{cal}} / R_{\text{obs}}$, respectively, the grain growth rate of the matrix is evaluated by

$$R^4 - R_0^4 = k^4_{\text{Matrix}} \cdot t = \left( \frac{\beta}{f^m} \right)^4 \cdot k_4^4 \cdot t \quad \text{(9)}$$

where $k^4_{\text{Matrix}}$ is the rate constant for the grain growth. However, it was found that the Zener relation in the steady state for Fe–1.9vol%Bi alloy is expressed by

$$R = \beta \cdot f^m / C \quad \text{..........................(10)}$$

Thus, the grain growth rate of the matrix can be written as

$$(R - C)^4 - (R_0 - C)^4 = k^4_{\text{Matrix}} \cdot t = \left( \frac{\beta}{f^m} \right)^4 \cdot k_4^4 \cdot t \quad \text{...(11)}$$

Figure 11 shows the fourth power of $(R - C)$ versus the annealing time $t$, where only experimental values on the steady state at long annealing times are used. $C = 14.1$ was taken from the intercept of Fig. 9. From the slope of Fig. 11, the experimental rate constant of the grain growth was experimentally observed at 1 173 K. The following results were obtained in the experiment.

1. Complete recrystallization of the Fe–Bi alloy was observed at 120 s.
2. Dragging of the liquid Bi particles induced by grain boundary migration was observed in the grain growth.
3. The grain growth of the Fe–Bi alloy was extremely restricted by the dragging of the liquid Bi particles.
4. The ripening of the intergranular particles in the Fe–Bi alloy at was controlled by volume diffusion of Bi atoms in the matrix phase.
5. The ripening of the intergranular particles in the Fe–Bi alloy was controlled by grain boundary diffusion of Bi atoms.
6. The grain growth of the matrix was controlled by the ripening of the intergranular particles.

A1. Numerical Data for Calculation of Intragranular Particles

Since there is no report on the impurity diffusion coefficient of Bi in αFe, the diffusion coefficient of Sn in αFe, \( D_s = \frac{D_{Sn,\alpha Fe}}{H_11005} = 3.2 \times 10^{-14} \text{ m}^2 \cdot \text{s}^{-1} \) was used instead of the \( D_{Bi,\alpha Fe} \). The \( \Delta \) value was on the order of 1.387 and \( B = 0.477 \) was estimated from the experimental data of Fe–1.9vol%Bi alloy annealed at 1 173 K for 4 d.

A2. Numerical Data for Calculation of Intergranular Particles

Since no data on the grain boundary diffusion coefficient of Bi in the αFe \( D_{gb} = \frac{D_{gb,Bi,\alpha Fe}}{H_11005} \) has been reported, the grain boundary diffusion coefficient of Sn in the αFe grain boundary, \( K_{gb,Sn,\alpha Fe} = 3.9 \times 10^{-19} \text{ m}^2 \cdot \text{s}^{-1} \) was used instead of \( K_{gb,Bi,\alpha Fe} \). The \( A \) value was on the order of 1.387 and \( B = 0.477 \) was estimated from the experimental data of Fe–1.9vol%Bi alloy annealed at 1 173 K for 4 d.
