Thermodynamics of the Kitaev honeycomb magnet $\alpha$-RuCl$_3$ is studied for different directions of in-plane magnetic field using measurements of the magnetic Grüneisen parameter $\Gamma_B$ and specific heat $C$. We identify two critical fields $B_c^{\text{AF1}}$ and $B_c^{\text{AF2}}$ corresponding, respectively, to a transition between two magnetically ordered states and the loss of magnetic order toward a quantum paramagnetic state. The $B_c^{\text{AF2}}$ phase boundary reveals a narrow region of magnetic fields where inverse melting of the ordered phase may occur. No additional transitions are detected above $B_c^{\text{AF2}}$ for any direction of the in-plane field, although a shoulder anomaly in $\Gamma_B$ is observed systematically at $8 - 10$ T. Large field-induced entropy effects imply additional low-energy excitations at low fields and/or strongly field-dependent phonon entropies. Our results establish universal features of $\alpha$-RuCl$_3$ in high magnetic fields and challenge the presence of a field-induced Kitaev spin liquid in this material.

The Kitaev honeycomb model offers a possible practical route toward a quantum spin liquid with exotic fractionalized excitations and potential applications in topological quantum computing [1, 2]. The 4d layered honeycomb material $\alpha$-RuCl$_3$ is one of the best experimental realizations of this model available so far [3–5]. However, it develops long-range magnetic order in zero magnetic field and may only be proximate to the elusive Kitaev spin liquid (KSL) [6, 7]. Tuning $\alpha$-RuCl$_3$ by pressure [8, 9] or chemical substitution [10] is hampered by unwanted effects of dimerization and magnetic dilution, respectively. On the other hand, magnetic fields applied within the honeycomb $(ab)$ plane can act as a very clean tuning mechanism that eliminates magnetic order above $B_c = 7.0 - 7.5$ T [11–13].

The physics within this region without magnetic order are subject of significant debate. On the one hand, a half-integer plateau in the thermal Hall conductivity (THC) as expected for the KSL phase has been reported [14]. However, spectroscopic measurements find excitations that are expected for the topologically trivial, partially-polarized phase [15–17]. To scrutinize this, recent studies compared the effects from rotating the magnetic field within the plane against the expectations for the KSL. For the Kitaev model under most in-plane field angles $\phi$, the KSL would be gapped and show a quantized THC with $\phi$-dependent sign. Yet for fields parallel to a bond ($\phi = n \cdot 60^\circ, n \in \mathbb{Z}$ [18]), the KSL would be gapless and show no THC. Experimentally, the sign structure of the THC was indeed observed in $\alpha$-RuCl$_3$ [19]. However, for in-plane fields, the same sign structure is expected for the partially-polarized phase, suggesting that the dependence of the THC with $\phi$ alone at the accessed temperatures cannot distinguish between the scenarios [20]. The gaplessness of the field-induced state for distinct $\phi$ (as predicted for the KSL) however would be a property clearly incompatible with the partially-polarized phase. Accordingly, the $\phi$-dependent gap was recently investigated by Tanaka et al. [21]. From analysis of their low-temperature specific heat measurements, a gapless behavior for $\phi = n \cdot 60^\circ$ and gapped behavior for $\phi \neq n \cdot 60^\circ$, as expected for the KSL, was reported [21].

Another pertinent question is the occurrence of a phase transition upon entering and leaving this putative QSL as a function of field. No conspicuous signatures of such transitions are found in recent studies using various thermodynamic probes [22, 23]. Here, we employ the magnetic Grüneisen parameter ($\Gamma_B$) and specific heat ($C$) to map out the field-angle, field-strength and temperature-dependent phase diagram of $\alpha$-RuCl$_3$. These demonstrate the absence of further phase transitions beyond the magnetically ordered region for any in-plane angle of the magnetic field. We furthermore uncover a finite region where inverse melting of the antiferromagnetic phase may occur and track shoulder-anomalies in $\Gamma_B$ within the quantum paramagnetic region. In addition, the combination of $\Gamma_B$ and $C$ allows to directly resolve entropy-differences between states at different field strengths and angles. These reveal an unexpectedly large loss of entropy from the zero-field gapped ordered phases to the quantum paramagnetic region, independent of in-plane angle of the field.

The field-dependent measurements of specific heat ($C$) and magnetic Grüneisen parameter ($\Gamma_B$) were performed in a dilution refrigerator using the relaxation method for $C$ [24] and the high-resolution alternating-field method
Our data shows two phase transitions as a function of field strength. The dominant feature is the sign change of \( \Gamma_B \) from negative to positive at \( B_{c1}^{AF} \), which is equivalent to an entropy maximum at a second-order phase transition. It marks the phase boundary between the long-range-ordered and quantum paramagnetic regions of \( \alpha\text{-RuCl}_3 \). A somewhat weaker signature identifies \( B_{c2}^{AF} \) as a first-order transition between two different antiferromagnetic (AF) ordered states [10] caused by a change in out-of-plane ordering [27]. In this case, the transition point is determined by a maximum in \( \Gamma_B(B) \), which is equivalent to a smeared negative step in the entropy. Note that Fig. 1 depicts the raw data of \( \Gamma_B(B) \) since subtraction of the cell background was not possible for all curves [24]. This neither affects the values of the critical fields \( B_{c1,2}^{AF} \), nor changes their evolution at high fields that will be discussed in the following.

Rotating the field strongly influences the positions of both \( B_{c1}^{AF} \) and \( B_{c2}^{AF} \), illustrating the in-plane anisotropy of the system (compare Fig. 1 (a)-(d)). This anisotropy is most pronounced for the [110]-direction (Fig. 1(a)), where already small changes of \( \phi \) influence \( B_{c1,2}^{AF} \). Both absolute values of the critical fields and their angular dependence match perfectly the results of previous ac-susceptibility measurements [27], where critical fields were determined from peaks in \( \chi' \). This validates our procedure for the evaluation of \( B_{c1}^{AF} \) and \( B_{c2}^{AF} \) and allows their measurement over a broad temperature range, as \( \Gamma_B \) is generally more sensitive to field-induced phase transitions than, e.g., specific heat.

We will take advantage of this unique sensitivity to probe the presence of field-induced phase transitions above \( B_{c1}^{AF} \), but first we discuss peculiarities of the critical fields \( B_{c1}^{AF} \) and \( B_{c2}^{AF} \) as a function of temperature. 

Fig. 2(a) shows the field-dependent raw data of \( \Gamma_B \) for several temperatures and the field applied along the [110]-direction. For \( T \geq 2 \text{ K} \), the critical field \( B_{c1}^{AF} \) (marked by the sign change of \( \Gamma_B \)) shifts to lower fields with increasing temperature. This behavior is expected, since the stability of a symmetry-broken phase \((B < B_{c1}^{AF})\) is usually decreased by temperature.
higher temperatures, the peak in the specific heat broadens, and the determination of $B_c^{AF2}$ from the peak position becomes less accurate than from the sign change in $\Gamma_B$. Temperature dependence of $B_c^{AF1}$ shows an overall similar behavior, except for the fact that the temperature dependence of $B_c^{AF1}$ is monotonic for $\vec{B} \parallel [10]$. The peculiarities of the phase boundaries are independently confirmed by field dependence of the magnetic entropy obtained as $\Delta S = -\int d\vec{B} \Gamma_B C$ using the Maxwell equation $(\partial S/\partial B) = (\partial M/\partial T)$ [Fig. 3]. The Clausius-Clapeyron equation requires that $dB_c^{AF1}/dT = -\Delta S/\Delta M$, where $\Delta S$ and $\Delta M$ are changes in, respectively, entropy and magnetization across the transition. Since $\Delta M > 0$, $dB_c^{AF1}/dT > 0$ implies $\Delta S < 0$, and indeed we observe the reduction in $\Delta S$ around $B_c^{AF1}$ for $\vec{B} \parallel [10]$ (Fig. 3(a)) but not for $\vec{B} \parallel [010]$ (Fig. 3(b)).

As likely no symmetry is broken for $B > B_c^{AF2}$, the non-monotonic phase boundary implies a narrow range of magnetic fields, near 7.0 T for $\vec{B} \parallel [10]$ and 7.6 T for $\vec{B} \parallel [010]$, where the system upon cooling first enters a magnetically ordered state (AF2) and at lower temperatures becomes disordered again. Such inverse melting behavior has been predicted theoretically for some anisotropic spin models [31–33]. It may therefore be an interesting future avenue for theory to also search for inverse melting in extended Kitaev models.

From the integrated entropy differences, we note that the total observed field-induced entropy release from zero field, $S(0 \text{T}) - S(14 \text{T}) \approx 0.65 \text{mJmol}^{-1} \text{K}^{-1}$ (here at $T = 1 \text{K}$, $\phi = 0^\circ$), appears to be much larger than the maximum magnetic entropy that one would expect in the zero-field antiferromagnetic phase with a gap $\Delta > 1.5 \text{meV}$ (inferred from inelastic neutron scattering [13, 34]) [35]. Therefore, there are either additional low-energy magnetic excitations at $B = 0$ below the resolution of neutron scattering [36, 37], and/or the significant magnetoelastic coupling of $\alpha$-RuCl$_3$ [22, 37–39] leads to a strongly field-dependent phonon entropy through magnetostriction-type effects.

Having established boundaries of the magnetically ordered phases in $\alpha$-RuCl$_3$, we now proceed to the evolution of the system in the quantum paramagnetic region above $B_c^{AF2}$. Here, several measurements of thermal Hall effect reported the half-integer plateau [14, 19, 40] — at $\sim 9 \text{T}$ to $\sim 11.5 \text{T}$ for $\vec{B} \parallel [10]$ [19] — and also suggested an extreme sensitivity of this measurement to the sample quality [40]. If this thermal Hall plateau originates from a gapped topological KSL as suggested by these reports, phase transitions to the bordering topologically trivial

**FIG. 2.** Field dependence of the magnetic Grüneisen parameter $\Gamma_B$ (raw data, see [24]) for several temperatures with the in-plane magnetic field $\vec{B}$ applied parallel (a) to [10], and (b) to [010]. $B_c^{AF2}$ is the point where $\Gamma_B$ changes sign and indicates the transition between long-range-ordered and quantum paramagnetic states of $\alpha$-RuCl$_3$ [23]. At higher temperatures, $B_c^{AF2}$ shifts towards lower fields due to thermal fluctuations. However, below 2 K an opposite behavior is observed, suggesting that the phase boundary is non-monotonic (c,d). The phase transition inside the AF state at $B_c^{AF1}$ is most likely of first-order and, thus, manifests itself in a maximum of $\Gamma_B$, which is clearly visible for $\vec{B} \parallel [10]$. By increasing the temperature the maximum is suppressed and gradually shifted toward lower fields. A very similar behavior is observed for $\vec{B} \parallel [010]$, yet the determination of $B_c^{AF1}$ is significantly more difficult due to the proximity to $B_c^{AF2}$ [24]. The discrepancy between the critical fields extracted from $\Gamma_B$ and the specific heat $C$ is explained in the main text.
phases should occur. These would happen either through gap closing or be first order. Our data firmly excludes the former possibility for α-RuCl$_3$, since no sign change from negative to positive is observed in $\Gamma_B$ above $B_{c}^{AF2}$ at any field direction [Fig. 1] and temperatures down to 0.5 K [Fig. 4]. Instead, $\Gamma_B$ appears to asymptotically approach zero at high field strengths for all angles [Fig. 1], which would be consistent with the behavior of a single partially-polarized phase above $B_{c}^{AF2}$. Before discussing the alternative scenario of a first-order transition out of a putative KSL, we inspect $\Gamma_B$ for further possible anomalies aside from sign changes.

The only conspicuous feature in $\Gamma_B$ at 1 K above $B_{c}^{AF2}$ is a shoulder for $\vec{B} \parallel [010]$, setting in at 9.3 T [Fig. 4, yellow symbols]. This can be paralleled to similar weak anomalies reported previously in the magnetocaloric effect ($\phi = 20^\circ$) [41] and magnetostriction ([010]) [38]. In contrast, for $\vec{B} \parallel [110]$, no clear shoulder is visible. However, a rather abrupt change of slope at $\sim 8.2$ T is present (Fig. 4, magenta dotted line), which can be interpreted as a shoulder superimposed on the rapidly decreasing $\Gamma_B \sim 1/(B - B_{c}^{AF2})$ in the vicinity of $B_{c}^{AF2}$ due to critical fluctuations [42]. Interestingly, a similar feature can be identified for [010], too [Fig. 4, yellow dotted lines]. By reducing the temperature to 0.5 K, these anomalies become more prominent, possibly with two shoulders for $\vec{B} \parallel [010]$ [inset Fig. 4]. Previously, we assigned such a shoulder feature to a level crossing in low-energy excitations [23]. Our data in Fig. 4 suggest that the field strength at which this occurs has only a weak dependence on the in-plane field direction, qualitatively consistent with an ab-initio-derived microscopic model of α-RuCl$_3$ [24, 39]. This observation is also in line with recent spectroscopic measurements suggesting only a weak dependence of Γ-point (q = 0) excitations on the direction of the in-plane field [16, 43].

While we ruled out a continuous transition above $B_{c}^{AF2}$, we now investigate the possibility whether these anomalies and/or other features in our data could support a first-order transition out of a KSL phase. Such a first-order scenario was put forward recently [21], where both the putative gapless ($\phi = 0^\circ$) and gapped ($\phi \neq 0^\circ$) KSLs would experience first-order transitions towards a gapped topologically trivial phase at $B \gtrsim 10$ T. We therefore examine field-dependent entropy changes, obtained as $\Delta S = -\int dB \Gamma_B C$. These are shown for $\phi = 30^\circ$ and $\phi = 0^\circ$ in Fig. 3, where each entropy curve has been shifted such that $\Delta S(14$ T) = 0 mJ K$^{-1}$ mol$^{-1}$. No anomalies are detected in $\Delta S$ above $B_{c}^{AF2}$ for either field direction and up to 14 T. For $\phi = 30^\circ$, the gap within the putative KSL would be the largest, such that a first-order transition to another phase with comparable gap may be hard to detect. However, for the putative gapless KSL along $\phi = 0^\circ$, one would expect significant latent heat to be released at a first-order transition to a gapped state,
which we however do not observe. Instead, entropy appears to shrink asymptotically with field strength, consistent with a continuously growing gap in a single partially-polarized phase above $B_c^{AF2}$.

In summary, our comprehensive thermodynamic study of $\alpha$-RuCl$_3$ revealed several universal features of this material that do not depend on the direction of the in-plane magnetic field. For the magnetically ordered phases $B \leq B_c^{AF1}$, the phase boundary separating them from the quantum paramagnetic state is non-monotonic, suggesting a narrow region of inverse melting. The in-plane anisotropy manifests itself in the different stability range of the intermediate ordered phase observed between $B_c^{AF1}$ and $B_c^{AF2}$. For the quantum paramagnetic region $B > B_c^{AF2}$, our data is clearly inconsistent with the existence of an additional continuous transition and also speaks against a first-order transition. This applies both for field angles where a gapless Kitaev spin liquid (KSL) and angles where a gapped KSL have been proposed, implying that the plateau in the thermal Hall conductivity in $\alpha$-RuCl$_3$ does not go along with a topologically nontrivial KSL. Instead, the observed thermodynamics are qualitatively consistent with a single phase above $B_c^{AF2}$ with a monotonically growing excitation gap.

We thank Yoshi Tokiwa for his experimental assistance during early stages of this work. Supplemental Material

Angle-dependent thermodynamics of α-RuCl₃

VARIATION OF IN-PLANE FIELD DIRECTION

The magnetic field orientation in the honeycomb plane of α-RuCl₃ was adjusted by tilting the cell, including the sample platform, using brass wedges with different angles [Fig. S1(a,b)]. The crystal was mounted with the honeycomb planes on the platform and the cell is attached to the cryostat sample holder, such that the magnetic field always points in the planes. Rotating the cell by the wedges results in a variation of the in-plane field angle. This way, we measured several configurations and determined the critical fields $B^{AF1,2}_c$. By comparing these results to ac-susceptibility measurements [1], we calibrated our field orientation relative to the [010] direction which we defined as $\phi = 0^\circ$. Here, we used the near six-fold symmetry which has further been validated by the angle-dependency of specific heat [2]. Note that our previously measured field direction $\phi = 20^\circ$ [3] as defined in the main text used the setup described in Fig. S1c. Strictly speaking, this corresponds to a value of $\phi = 100^\circ$, which is equivalent to $\phi = 20^\circ$ in the angle-field phase diagram [Fig. 1, main text]. In the same way, $\phi = -5^\circ$ is equivalent to $\phi = +5^\circ$. The excellent agreement of our angle-field phase diagram with the ac-susceptibility measurements further approves the six-fold symmetry of the $B^{AF1}_c$ and $B^{AF2}_c$ transitions.

CELL BACKGROUND CONTRIBUTION FOR MAGNETIC GRÜNEISEN PARAMETER $\Gamma_B$ BELOW 1 K

Samples with a small heat capacity compared to that of the cell require a careful background subtraction for the Grüneisen parameter $\Gamma_B$. First, the total value $\Gamma_{B,\text{tot}}$ has to be measured which includes both cell and sample contributions. Second, the heat capacities $C_{\text{Sa}}$ and $C_{\text{Cell}}$ of, respectively, the sample and cell are needed. Together with $\Gamma_{B,\text{Cell}}$, the sample’s Grüneisen parameter is calculated according to Ref. [3]:

$$\Gamma_{B,\text{Sa}} = \Gamma_{B,\text{tot}} + \frac{C_{\text{Cell}}}{C_{\text{Sa}}} (\Gamma_{B,\text{tot}} - \Gamma_{B,\text{Cell}}).$$  \hspace{1cm} (S1)

As a result, the background subtraction is not feasible in the absence of $C(B)$. Considering huge time requirements for such a measurement, as opposed to the measurement of $\Gamma_B$, we chose not to perform it for each temperature and

![Fig. S1. (a) Rotation of Grüneisen and specific heat setup by using brass wedges with the angles $\alpha = 10/15/20^\circ$. The sample is mounted with the honeycomb planes being parallel to the sample platform ($c^\parallel$ perpendicular to sample platform, magnetic field orientation indicated in the sketch). (b) Angles of $\pm 5/25/30^\circ$ can be achieved by combining two wedges. In this way, rotating the cell by $\pm 30^\circ$ in $5^\circ$ steps is realizable. Consequently, the magnetic field is orientated in different directions in the honeycomb planes. Note, however, that $\alpha$ is not equivalent to $\phi$ from the main text. We used the wedges to align the sample with several in-plane field directions. Afterwards, we determined the respective field orientation $\phi$ relative to the [010] direction which we calibrated using the critical fields $B^{AF1,2}_c$ from ac-susceptibility [1], see Fig. 1 in the main text, together with the near six-fold symmetry [1, 2]. The in-plane field direction $\phi = 20^\circ$ as defined in the main text was measured previously [3] with the configuration shown in (c). Strictly speaking, this corresponds to a value of $\phi = 100^\circ$ which is equivalent to $\phi = 20^\circ$ in the angle-field phase diagram [Fig. 1, main text]. In the same way, $\phi = -5^\circ$ is equivalent to $\phi = +5^\circ$.](image-url)
field direction and used the raw data in our analysis.

In Fig. S2, we show exemplary background subtraction for $\Gamma_B$ at 1 K. One sees that the cell background is negligible in the vicinity of $B_c^{\text{AF1}}$ and $B_c^{\text{AF2}}$, so the raw data can be safely used for the determination of critical fields. The background contribution becomes more significant above $B_c^{\text{AF2}}$, where specific heat of the sample decreases. Here, the background is responsible for the apparent negative values of $\Gamma_B$ above $10 - 12$ T, while positive values are recovered once the background contribution is subtracted. Therefore, we argue that $\Gamma_B$ of the sample remains positive even well above $B_c^{\text{AF2}}$. We also note that, should any phase transitions occur above $B_c^{\text{AF2}}$, they would of course show up also in the raw data.

**MORE DETAILS ABOUT $\Gamma_B$**

Here, we present our Grüneisen parameter study in more detail. Fig. S3 illustrates the whole field range from 0 to 14 T for the field applied along (a) [110] and (b) [010] at 1 and 2 K, respectively. As already discussed before, the main signatures result from $B_c^{\text{AF}}$ and $B_c^{\text{AF1}}$, the latter being weakest for [010]. The sign change due to an entropy maximum at $\sim 2$ T from [3] is reproduced and likely related to domain reconstruction, as reported previously [4].

Now, we focus on establishing the temperature-field phase diagram from the main text [Fig. 2]. In Fig. S4, all measured temperatures are shown for (a,b) [110] and (c,d) [010], respectively. Determining $B_c^{\text{AF2}}$ as transition from the AF to the field-polarized state is straightforward due to the obvious sign change from negative to positive. In contrast, $B_c^{\text{AF1}}$ can not always be identified with comparable accuracy. For [110] at temperatures up to 2.5 K, the maximum indicative of the first-order transition is clearly visible [arrows in Fig. S4(a)]. However, this maximum broadens towards higher temperatures and eventually becomes almost completely smeared out at 4 K. At this point, $B_c^{\text{AF1}}$ is defined by the remaining kink [arrow in Fig. S4(b)]. Above that temperature, even this kink fades away. With the field oriented along [010], establishing $B_c^{\text{AF1}}$ is even more challenging because of the proximity to the dominant feature at $B_c^{\text{AF2}}$. At 1 K, $B_c^{\text{AF1}}$ appears as a broad shoulder, which evolves into a maximum at higher temperatures, e.g. 2 K [arrows in Fig. S4(c)]. Yet, it can not be identified any more below 1 K. Similarly to [110], the maximum transforms into a kink at higher temperatures [Fig. S4(d)] and eventually vanishes.

Finally, the field-evolution of the Grüneisen parameter at 1 K and 500 mK is shown in Fig. S5 for several field orientations. At 1 K in Fig. S5(a), $\phi = 20^\circ$ reveals a plateau at similar position like [010]. Furthermore, the weaker anisotropy along [010] is corroborated because rotating by $\phi = 5^\circ$ does not change $\Gamma_B(B)$ significantly compared to [010]. At 500 mK, the cell background can not be subtracted as explained above. A minimal difference between $\phi = \pm 5^\circ$ directly below $B_c^{\text{AF2}}$ might indicate that $\phi = 0^\circ$ is not perfectly aligned along [010]. Nonetheless, this misalignment should be smaller than $2^\circ$. Aside from this small deviation, the data for $\pm 5$ and $0^\circ$ are almost perfectly on top of each other, further confirming the weaker anisotropy along the [010] direction. Fig. S5(c) represents the

**FIG. S2.** (a) Cell background subtraction for [110] at 1 K following Eq. (S1). Raw data denote the Grüneisen parameter from both cell and sample. For the background measurement, $\Gamma_{B, \text{Cell}}$ was measured independently. Despite the subtraction, the positions of $B_c^{\text{AF1}}$ and $B_c^{\text{AF2}}$ are unaffected. This fully justifies using the raw data for constructing the phase diagram in the main text. (b) Influence of the cell background at high fields. Here, the sample exhibits a specific heat $C$ and Grüneisen parameter $\Gamma_B$ comparable to the background (see also [3]). As a consequence from the negative background, the raw data cross zero at higher fields, too (open circles). However, after subtraction, the Grüneisen parameter $\Gamma_{B, Sa}$ of the sample remains positive (full circles).
In this part, we present field-dependent heat capacity measurements below 1 K. First, we focus on the phase transitions $B_{c}^{AF1}$ and $B_{c}^{AF2}$. Second, we discuss the influence of nuclear contribution on the results above $B_{c}^{AF2}$. Finally, we conclude with a comment about the analysis at low temperatures and high fields in our setup, and how this influences a potential determination of a small gap.

In Fig. S6(a), shows the field-dependent heat capacity of the $\alpha$-RuCl$_3$ crystal at 500 mK for several directions in absolute units of $\mu$J/K since no cell background subtraction was possible, as explained in more detail below. The phase transition at $B_{c}^{AF2} \sim 7 - 7.6$ T is perfectly resolved as a peak for all field orientations. For [110], a second maximum indicative for $B_{c}^{AF1}$ is clearly visible and used as well for the phase diagram in the main text. In a similar manner, the heat capacity data at 200 mK and [110] orientation are interpreted [Fig. S6(b)]. Both $B_{c}^{AF1}$ and $B_{c}^{AF2}$ are undoubtfully identifiable.

Now, we turn to the 500 mK data [Fig. S6(a)]. Towards higher fields a strange monotonic increase is observed, its origin will be discussed below. Notwithstanding this spurious effect, no additional anomaly can be seen above $B_{c}^{AF2}$ for any field direction, also for the 200 mK data in the field along [110]. Therefore, we conclude that our heat capacity data show the absence of further transitions beyond $B_{c}^{AF2}$ for all measured field directions.

In the following, we focus on the reason for the unphysical heat capacity behavior far above $B_{c}^{AF2}$. We attribute this to the presence of nuclear contribution in our setup. This contribution is enhanced in high magnetic fields and becomes comparable to the small sample heat capacity in the order of several $\sim 10$ nJ/K. Combined with a sizable spin-lattice relaxation time this may give rise to the so-called $2\tau$-effect [5, 6] and causing discrepancies when standard analysis with a single exponential function is used. Obviously, as shown in Fig. S6(c-f), such deviations only occur at fields far beyond $B_{c}^{AF2}$, which is unambiguously visible in the logarithmic plots (insets). Consequently, the analysis using the single exponential function results in unreasonable behavior. We assign the nuclear contribution to the sapphire platform (Al$_2$O$_3$) due to the nuclear moments of Al because the background measurement without sample revealed very similar behavior. Accordingly, a precise analysis of the cell background was impossible, too, preventing a background subtraction in Fig. S6(a,b).

As a result, due to this problem below 1 K and at high fields, our heat capacity data do not allow to determine the excitation gap under high magnetic fields. The framework beyond Refs. [5, 6] would be needed to ensure an appropriate subtraction of the nuclear contribution and goes beyond the scope of our present work.
FIG. S4. Detailed $\Gamma_B$ measurements used for the determination of $B_c^{\text{AF1}}$ and $B_c^{\text{AF2}}$ for (a,b) [110] and (c,d) [010]. Raw data without cell background subtraction are shown, because corresponding specific heat data were not always available. This does not affect the positions of $B_c^{\text{AF1}}$ and $B_c^{\text{AF2}}$, as explained in the text. The transition $B_c^{\text{AF2}}$ is easily identified as the sign change from negative to positive for all temperatures and field directions. (a,b) [110] direction. The maximum indicative of $B_c^{\text{AF1}}$ is clearly visible at temperatures below 2.5 K (black and orange arrow) and broadens toward higher temperatures, transforming into a kink at 4 K (purple arrow), and finally vanishes. (c,d) [010] direction. Here, the determination of $B_c^{\text{AF1}}$ is hindered by the proximity to the dominant transition at $B_c^{\text{AF2}}$. The 2 K data show a maximum (red arrow) that develops into a broad shoulder at 1 K (black arrow), and becomes fully screened by the increasingly sharp feature at $B_c^{\text{AF2}}$ toward lower temperatures. Above 2.5 K, the maximum becomes a kink (orange and purple arrow) and vanishes, similarly to the [110] orientation.

**COMPARISON TO EXTENDED KITAEV MODELS**

To compare our measurements of $\Gamma_B$ to expectations from such extended Kitaev models, we employ exact diagonalization on a two-dimensional 24-sites honeycomb cluster with $C_3$ symmetry. To access $\Gamma_B$ at small finite temperatures, we follow the method applied for the theoretical calculations in Ref. [3]. While these two-dimensional calculations cannot capture the transition $B_c^{\text{AF1}}$ related to the change of the out-of-plane ordering wave vector, other properties like $B_c^{\text{AF2}}$, the magnitude and sign of $\Gamma_B$ and possible occurrences of shoulder anomalies may be compared qualitatively.

In extended Kitaev models, the three nearest-neighbor bonds of the honeycomb lattice are defined as $X_1$, $Y_1$, $Z_1$ bonds depending on their orientation. Second-neighbors $X_2$, $Y_2$, $Z_2$ (third-neighbors $X_3$, $Y_3$, $Z_3$) bonds within the plane are then defined as those orthogonal (parallel) to the directions of the respective $X_1$, $Y_1$, $Z_1$ bonds. The effective magnetic Hamiltonian for $Z_n$-bonds ($n \in \{1, 2, 3\}$) then reads

$$H_{Z_n} = \sum_{\langle ij \rangle_{Z_n}} J_{n} \mathbf{S}_i \cdot \mathbf{S}_j + K_n S_i^z S_j^z + \Gamma_n \left( S_i^x S_j^y + S_i^y S_j^x \right) + \Gamma_n' \left( S_i^x S_j^x + S_i^y S_j^y + S_i^z S_j^z \right),$$

with effective spin-$\frac{1}{2}$ operators $\mathbf{S}_i$. The Hamiltonians for $X_n$ and $Y_n$ bonds can be obtained by cyclic permutation.
of spin components \((x, y, z)\) in Eq. (S2). Furthermore, a Zeeman term \(H_{\text{Ze}} = -\mu_B \sum_i \mathbf{B} \cdot \mathbf{g} \cdot \mathbf{S}_i\) can contribute with magnetic field \(\mathbf{B}\) and the \(g\)-tensor \(\mathbf{g}\). If \(K_1\) is the only finite exchange coupling and \(\mathbf{B} = 0\), the model reduces to the exactly solvable Kitaev honeycomb model.

We discuss two representative models that have been shown to be qualitatively consistent with numerous experimental observations in \(\alpha\)-RuCl\(_3\). Fig. S7(a,b) shows results for \(\Gamma_B\) for the model of Ref. [7], whose nonzero magnetic couplings are \((J_1, K_1, \Gamma_1, J_3) = (-0.5, -5, 2.5, 0.5)\) meV and where \((g_{ab}, g_{c^*}) = (2.3, 1.3)\). Fig. S7(c,d) shows results for the ab-initio parameters of Ref. [8], \((J_1, K_1, \Gamma_1', \Gamma_2, \Gamma_2', J_3, K_3, \Gamma_3, \Gamma_3') = (-5.66, -10.12, 9.35, -0.73, -0.18, 0.06, 0.03, 0.2, 0.25, 0.04, -0.07)\) meV and \(g_{ab} = 2.36\), where we omitted weak second-neighbor \(J_2\) and Dzyaloshinskii-Moriya exchanges. Both models feature zigzag antiferromagnetic order at zero magnetic field and a single phase transition under in-plane magnetic fields to a partially-polarized phase. Within the antiferromagnetic phase, \(\Gamma_B\) is found to be negative up to the critical fields (corresponding to the suppression of magnetic order, \(B_{c}^{\text{AF}2}\)) near to 6 Tesla. At these critical fields, a sign change in \(\Gamma_B\) occurs. The fact that \(\Gamma_B\) does not diverge at \(B_{c}^{\text{AF}2}\) and only shows a delayed maximum at higher field strengths is likely a finite-size effect of the calculation, as the gap can not fully close at a continuous transition on a finite cluster. Various universal features found in our measurements are nevertheless captured qualitatively: The field strength at which the sign change takes place follows the correct dependence on the in-plane angle in both models [blue vertical lines in Fig. S7], with highest magnetic fields for \(\phi = 0^\circ\) and lowest for \(\phi = 30^\circ\). While the model of Ref. [7] shows no anomalies beyond the sign change and maximum in \(\Gamma_B\), the model of Ref. [8] features shoulder-anomalies at higher field strengths [orange vertical lines in Fig. S7(c,d)]. Such anomalies are found in various extended Kitaev models that are proximate to competing phases at finite fields, but do not enter them [3]. They occur as a result of field-induced level crossings in the lowest excited states within the partially-polarized phase and appear as a negative jump in \(\Gamma_B\) for \(T \to 0\) K, that is smeared out at finite temperatures. In the present model of Ref. [8], both the position of the sign change, and that of the should-anomaly are found to shift to lower field strengths upon rotating from \(\phi = 0^\circ\) to \(\phi = 30^\circ\). This behavior is qualitatively consistent with the anomalies observed in experiment [Fig. 4 of main text], however in the present set of ab-initio parameters occurs at much higher field strengths. This might be a result of finite-size effects and/or could be refined by adjusting these parameters. We also checked the effect of magnetic fields perpendicular to the honeycomb plane (\(\mathbf{B} \parallel c^*\)) [black points in Fig. S7(a)]. In accordance with our measurement, the Grüneisen parameter is found to be approximately zero for this direction (up to field strengths of \(\sim 33\) T in the model of Ref. [7]).

FIG. S6. (a) Field dependence of the total heat capacity $C_{\text{tot}}$ (including background) up to 14 T for several field orientations. They perfectly match the 1 K data from the main text, undoubtedly resolving $B_{c}^{\text{AF}2}$ and, in the case [110], also $B_{c}^{\text{AF}1}$. Far above $B_{c}^{\text{AF}2}$, fitting with a single exponential function is not adequate anymore resulting in the unphysical increase towards higher fields due to shortcomings of the single exponential function analysis. Nevertheless, we speculate that a phase transition beyond $B_{c}^{\text{AF}2}$ would give rise to a deviation of the monotonic behavior, e.g., in form of another peak. As a consequence, from these data, we suspect that a phase transition seems to be unlikely. (f) Heat capacity for [110] at 200 mK. $B_{c}^{\text{AF}1}$ and $B_{c}^{\text{AF}2}$ are perfectly resolved while the monotonic behavior beyond $B_{c}^{\text{AF}2}$ does not indicate any further phase transition. (c-f) Examples for the sample temperature response $T(t)$ at 500 mK and different magnetic fields, all applied along the [110] direction. A single exponential function describes $T(t)$ very well for lower fields of e.g. (a) 3.2 T and (b) 7 T, respectively. At higher fields well beyond the phase transition $B_{c}^{\text{AF}2}$, the single exponential fit obviously deviates from the data points at (c) 10 T and (d) 12.6 T, respectively. This is even more obvious in the logarithmic plot in the insets where obviously two time constants are present, manifesting themselves in different slopes.
