The association between occupational loading and spine degeneration on imaging – a systematic review and meta-analysis

Luciana G. Macedo1* and Michele C. Battié2

Abstract

Background: There are inconsistencies in findings regarding the relationship of occupational loading with spinal degeneration or structural damage. Thus, a systematic review was conducted to determine the current state of knowledge on the association of occupational loading and spine degeneration on imaging.

Methods: We performed electronic searches on MEDLINE, CINAHL and EMBASE. We included cross-sectional, case control and cohort studies evaluating occupational loading as the exposure and lumbar spine structural findings on imaging as the outcomes. When possible, results were pooled.

Results: Seventeen studies were included in the review. Ten studies evaluated the association of occupational loading with disc degeneration (signal intensity), four of which were pooled into a meta-analysis. Of the 10 studies, only two did not identify a relationship between occupation loading and disc degeneration. A meta-analysis including four of the studies demonstrated an association between higher loading and degeneration for all spinal levels, with odds ratios between 1.6 and 3.3. Seven studies evaluated disc height narrowing and seven evaluate disc bulge, with six and five identifying an association of loading and with imaging findings respectively. Three studies evaluated modic changes and one identified and association with occupational load.

Conclusions: There was moderate evidence suggesting a modest association between occupational loading and disc degeneration (signal intensity), and low-quality evidence of an association between occupational loading and disc narrowing and bulging.

Keywords: Occupational load, Spine degeneration, Disc degeneration, Disc height, Imaging, Magnetic resonance imaging, X-ray

Background

The cumulative or repetitive injury model was once a dominant paradigm of spine degeneration [1]. Thus, heavy occupational physical loading activities have long been suspected of increasing spine degeneration. However, inconsistencies between study findings, with some supporting this association [2, 3] and other not [4, 5], have led to controversy and uncertainty about the relationship between physical loading and lumbar spine degeneration. Furthermore, recent studies suggest that the structures of the spinal column, including the intervertebral discs, adapt and may even benefit from greater routine physical loading [1].

Controversy still exists between the relationship of occupational load and low back pain [6]. However, given the subjective nature of pain evaluation and the high prevalence of back pain in general, studies depicting the association between pain and occupation load always have large room for bias. The use of objective measures of spine degeneration to evaluate the impact of occupational load on the spine can provide a solution to better

understanding this relationship. The evaluation of spine degeneration on imaging is both a reliable and objective measure to evaluate the effects of repetitive load on the spine, which in turn may mediate the occurrence of back pain in this population. Although spine degeneration on imaging is not synonymous with back pain, spine degeneration on imaging have been found to be associated with an increased risk for low back pain [7] and increased risk of recurrent episodes [8].

Given the inconsistencies in the literature about the association of occupational load and spine degeneration, the objective of this study was to systematically review the literature on the association of occupational loading and spine degeneration observed on imaging. Occupational loading was described as loading conditions occurring during occupational activities, such as lifting and manual handling or comparisons between specific occupations.

Methods
A protocol for the study was developed a priori following the PRISMA guidelines and Cochrane Handbook.

Data sources and searches
A computerised electronic search was performed to identify relevant articles. The search was conducted on MEDLINE (1946 to May 2019), CINAHL (1982 to May 2019) and EMBASE (1988 to May 2019). Key words included in our search were related to 3 domains: imaging (i.e. x-ray, radiograph), imaging findings (i.e. disc degeneration, disc height) and load (i.e. manual handling, occupational load). Subject subheadings and word truncations specific for each database were used. There was no language restriction. See Additional file 1 for search strategy section.

Two reviewers screened search results (titles and abstracts) for potentially eligible studies. A third independent reviewer resolved any disagreement for inclusion of trials. Authors were contacted if more information about the trial was needed to allow inclusion of the study.

We also performed a search on the reference lists of the included studies and a search on ISI Web of Science (May 2019) for papers that cited the included studies.

Study selection
Cross-sectional, case-control and cohort studies evaluating occupational loading as the exposure were eligible for inclusion. All studies that evaluated professional athletes and whole body vibration as a form of exposure were included on a separate review. In addition, the study had to evaluate the relationship of loading with lumbar spine structural findings evaluated on diagnostic imaging. Studies that used back pain as an outcome measure were not included. Studies that included patients with pre-existing conditions, such as disc herniation, were excluded from the review as they are more likely to have positive findings on imaging and may provide biased estimates for the relationship under investigation. Two reviewers screened the full text of potentially eligible studies and decided on inclusion. A third independent reviewer resolved any disagreement for inclusion of studies. The reviewers followed a research protocol developed prior to the beginning of the review, which included a checklist of inclusion criteria.

Data extraction and quality assessment
The methodological quality of the trials was assessed using the Newcastle Ottawa Quality Assessment scale [9, 10] for case-control and cohort studies. The maximum value of the scale is 9 (high quality) and the minimum value is 0 (lowest quality). The quality was assessed by independent raters and disagreements were resolved by a third rater. Methodological quality was not an inclusion criterion but was taken into consideration when making conclusions.

Two independent reviewers (LM and research assistants) extracted data from the included studies using a standardized data extraction form. Important characteristics of each study were extracted, such as type of loading, study design, type of imaging, patient population, affiliation of the authors, funding source, and study conclusions. We also extracted the type of outcomes used, and for continuous outcome measurements we extracted mean scores, standard deviations and sample size, and for dichotomous and ordinal outcomes, sample size and number of events per group.

Data synthesis and analysis
Results were pooled when trials were considered sufficiently homogenous with respect to participant characteristics, exposure and outcomes. I² was calculated using RevMan 5 to assess statistical heterogeneity. A random effects model was used to pool all available outcomes. I² was calculated to evaluate statistical heterogeneity of pooled outcomes [11]. When adequate data were presented from the original study, mean differences and standard deviations for continuous outcomes and odds ratios for dichotomous outcomes were calculated. When such information was not available, the information presented in each study was used for interpretation of the results.

The GRADE approach for grading the level of the evidence available was used to summarize the conclusion of this review [11]. Depending on the number and quality of the studies included in the review, the evidence was classified into high, moderate, low or very low quality evidence.
Results

Study selection

The electronic database search resulted in a total of 5363 articles after removing duplicates. Of these, 137 were selected as potentially eligible based on their title and abstract.

After full title screening a total of 16 studies were included in the review. An additional ISI web of science search showed 11 more potentially eligible studies, from which 1 was included in the review. Therefore, the final number of included studies was 17. (Flowchart Fig. 1).

125 Exclusion for graph only * 27 No outcome of interest [6, 10, 12–30, 31–35], 11 no non-exposed group [36–46], 23 not evaluating occupational load [1, 47–53, 54–62], 19 not a cohort study [63–81], 11 included patients on already established conditions, [37, 82–91] 5 no imaging on all groups [92–96], 4 cervical spine [97–100], 1 in vitro, [101] 1 child study [34], 1 cant get full text [102], 3 secondary analysis or study with same population of an already included study, [103–105] 10 studies evaluated whole body vibration alone, [106–115] 9 studies evaluated athletes [116–124].

Study characteristics

There were 16 original studies evaluating occupational load [2–5, 125–136] including 1 follow-up study [137]. Ten studies evaluated specific job requirements such as occupational lifting or job load summary score [2, 4, 127–130, 132, 133, 135–137] and six compared different types of occupation with different occupational requirements [3, 5, 125, 126, 131, 134]. See Table 1 for study characteristics.

Methodological quality

The methodological quality demonstrated an overall moderate level of quality, with a minimum of 3, a maximum score of 8, and a median and interquartile range of 5 and 3. The items of the methodological quality scale that were not present in most studies were control of potentially confounding factors and reporting of the response rate of each group.

Three studies included the same population from the Finnish Twin Spine study, but answered different questions related to different outcomes. These studies represent the strongest form of evidence given that controls are identical twins, minimizing possible confounding and familial aggregation [127, 128].

Outcomes

Ten studies evaluated the impact of loading on disc degeneration, generally assessed through disc signal intensity, representing disc desiccation [2–5, 126–129, 136].

($n = 164$, 53 drivers, 51 carpenters and 60 office workers). Participants were between 40 and 45 years old.                                                               |
| Munoz-Gomez et al. 1980 | 5                  | x-ray   | Cross sectional                      | Workers from an industry. All participants were between 19 to 63 years of age.                                                                                                                                               |
| Riihimaki et al. 1990 | 6                 | x-ray   | Cross sectional                      | $N = 417$ Male workers. 216 concrete reinforcement workers of an specific area were included and 201 house painters from a local union. Painters were matched with concrete workers based on a 5-year strata. Participants were between 25 to 54 years of age. |
| Savage et al. 1997 | 4                      | MRI     | Cross sectional (only 60% participated in the longitudinal cohort) | Volunteers from different occupations. $N = 149$ (24 ambulance men, 16 hospital porters, 40 car production workers, 12 brewery drayman and 57 office workers). All participants were between 20 and 58 years of age and were divided in two groups 20–30 and 31 to 58 years. |
| Schenk et al. 2006 | 7                      | MRI     | Cross sectional - case control       | $N = 109$ staff of local hospital that worked at least 20 h per week (57 nurses and 52 administration workers). All participants were between 45 and 62 years old.                                                                 |
The primary method of evaluating disc degeneration is through observing disc signal intensity on imaging. Disc degeneration is often associated with a whiter less translucent appearance of the disc [126]. Of these 10 studies only two did not find significant differences between groups [3, 129] and one study found more degeneration in those with less load [127]. In one study we were not able to assess whether statistical differences existed [134]. Seven studies identified some significant difference between loading groups with more load being associated with more degeneration, although we were not able to pool the results given the differences in types of loads and outcomes measured [2, 4, 5, 126–128, 133]. For all comparisons odds ratios when calculated varied between 1.89 to 3.7. A summary of the findings is presented in Table 2. One additional study looked at an overall measure of degeneration that included a combination of factors, and found that occupational loading was associated with the overall degeneration measurements [130].

We were able to pool the results of 4 studies evaluating the association of disc degeneration with different types of occupational load for different spine levels [2–4, 133]. The results demonstrated that for all levels evaluated, including L1-S1, there was a statistically significant difference between loading groups with more degeneration associated with greater loading. Forest plots are presented in Fig. 2.

Seven studies evaluated disc height [2, 125, 127, 128, 131, 133, 137]. Disc height can be measured on imaging using quantitative or qualitative measures and is a surrogate measure of disc degeneration. Of the seven studies evaluating disc height only one did not find a significant difference in disc height between groups [2]. The other six studies identified some type of influence of occupation load with disc height, with greater load being associated with narrower discs. Four studies identified an overall relationship of loading with disc height, without focusing on specific levels [125, 127, 128, 137] and the other studies found different levels to be significantly different [131, 133].

Seven studies evaluated a difference in the prevalence of disc bulge or herniation [3, 126, 128, 130, 133, 136, 137]. Disc bulges or herniations were primarily evaluated through visual observation of images. Of the seven studies, five identified a significant difference between loading groups [3, 128, 133, 136, 137]. Three studies evaluated the prevalence of all lumbar levels together [128, 136, 137] while two studies found difference for different levels, [3, 133] which varied between the studies. When calculated, odd ratios varied between 2.0 to 3.1.

Three studies evaluated Modic changes [126, 129, 135]. Modic changes represent lesions of the vertebral endplate that is adjacent to the bone marrow. Modic changes are often assessed qualitatively [135]. In this review only one study [135] identified a relationship of modic changes with occupation load. One study evaluated the prevalence of Schmorl's nodes [132]. These are small protrusion of the disc into the vertebral body. The one study included in this review did not identify a relationship of nodes with occupational loading groups. Two studies evaluated the presence of other endplate abnormalities, [125, 137] with only one study identifying a difference between loading groups [137]. Finally, three studies evaluated the presence of osteophytes [125, 132, 137] with two studies identifying greater prevalence of osteophytes in those with greater load [125, 137].

**Discussion**

The results of this study suggest that there is moderate grade evidence of an association between occupational loading and disc degeneration in terms of signal intensity. There is low quality grade evidence between loading and disc height, with inconsistent results between levels. There is low quality evidence for an association of disc bulging with occupational loading, again with inconsistent results among spinal levels. There is low quality evidence of an association between occupational loading and osteophytes, Modic changes, Schmorl's nodes and other endplate abnormalities.
| Study                  | Type of loading or exposure                                                                 | Outcomes                                                                 | Study results and RevMan analysis                                                                                       |

L2 L3 ($OR = 0.55 95\% CI 0.16 to 1.96$), L3 L4 ($OR = 1.5 95\% CI 0.66 to 3.42$), L4 L5 ($OR = 2.04 95\% CI 1.35 to 3.08$) and L5S1 ($OR = 1.30 95\% CI 0.70 to 2.43$) |
| Savage et al. 1997    | ambulance workers, hospital porters, car production workers, brewery dryman and office workers | Disc degeneration (signal intensity) (all levels together)                 | RevMan: There was no difference between groups in relation to disc degeneration. Car production vs office workers ($OR = 1.00 95\% CI 0.34 to 2.94$), hospital porters vs office workers ($OR = 1.63 95\% CI 0.45 to 5.91$) |
| Study                  | Type of loading or exposure                                                                 | Outcomes                                          | Study results and RevMan analysis                                                                                                                                                                                                 |
|-----------------------|---------------------------------------------------------------------------------------------|---------------------------------------------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Schenk et al. 2006    | nurses and office workers                                                                  | Disc degeneration (signal intensity) (1–5)         | RevMan: Disc degeneration was different between occupational groups for grade 2 with more degeneration in nurses (OR = 1.89; 95% CI 1.34 to 2.66, n = 544 all levels) and grade 4 with more degeneration in office workers (OR = 0.50 95% CI 0.29 to 0.86). There was no difference for grade 3 (OR = 1.14 95% CI 0.80 to 1.64) and grade 5 (OR = 0.75 95% CI 0.37 to 1.52), |
| Videman et al. 2007   | Job code (1–4), History of lifting at work (1000 kg)                                        | Disc signal intensity (L1-S1)                      | There was a significant association between history of lifting at work and signal intensity in the opposite direction (better signal with more load (Regression coefficient 0.001, p = 0.002), there was no association of occupational loading scoring and disc degeneration. |
| Battie et al. 1995    | job code (1–4), total occupational lifting (day), mean time working twisted/bent, mean time sitting at work, occupation driving (hr lifetime) | Disc height                                       | There was an association between job code (0-4), occupational lifting and occupational sitting with disc height but the association was not strong (r = -0.22)                                                                                             |
| Biering-Sorensen et al. 1985 | work is sedentary, light manual or heavy manual; worker undertakes heavy manual work, amount of physical activity at work | Disc height (for each level from L1 to S1)        | There were no significant differences for disc height                                                                                                                                                                                                                                           |
| Brinckmann et al. 1998 | Different occupations such as mining, steelworkers and normative data of unexposed individuals | Disc height (for each level from T12 to T1)       | Occupational loading was associated with a smaller disc height at a few spinal levels, particularly in those working in underground mines.                                                                                                                                                      |
| Hung et al. 2014      | Workers that carry heavy loads divided into low, intermediate and moderate lifting loads.   | Disc height narrowing (Farfan method. L4 L5 and L5S1) | RevMan: There were significant differences between groups for disc height narrowing at L5S1 (OR = 5.8 (2.7 to 13.6)).                                                                                                                                                      |
| Riihimaki et al. 1990 | Concrete reinforcement workers and house painters                                          | Disc space narrowing (0–5 for each level)         | RevMan: Concrete workers had greater disc height narrowing overall (OR = 2.19; 95% CI 1.34 to 3.58), L3 L4 (OR = 5.34; 95% CI 1.17 to 24.39) and L4 L5 (OR = 2.54; 95% CI 1.26 to 5.11) than painters. There was no difference at L1 L2 (OR = 2.84 95% CI 0.57 to 14.25), L2 L3 (OR = 0.93 95% CI 0.13 to 6.66) and L5S1 (OR = 1.35 95% CI 0.73 to 2.48). |
| Videman et al. 2006   | Job code (1–4), occupational driving, maximum weight lifted at work (kg)                   | Disc height narrowing                              | There was an association between occupational lifting and changes in degeneration over 5 years. (0.1 points/disc decrease in disc height = 0.021)                                                                                                                                       |
| Videman et al. 2007   | Job code (1–4)                                                                              | Disc height T12-S1                                 | There was an association between lifetime occupational loading score and disc height (regression coefficient 0.038, p = 0.004) and no association between history of lifting at work and disc height.                                                                 |
| Munoz-Gomez et al. 1980 | Work load calculated as above or below the general average                                | Degeneration (osteophytes, disc bulge and costotransversal arthritis) | RevMan: Those with occupational load greater than the average had greater degeneration (OR = 1.63; 95% CI 1.03 to 2.57).                                                                                                                                                      |
### Table 2 Exposure and results of each study included in the review that evaluated occupational load (Continued)

| Study                  | Type of loading or exposure                                                                 | Outcomes                                                                 | Study results and RevMan analysis                                                                                                                                 |
|------------------------|----------------------------------------------------------------------------------------------|--------------------------------------------------------------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Arevalo et al. 2014    | Heavy physical work activities                                                                | Disc herniation                                                          | There was an association between heavy physical work and disc herniation (OR = 2.0; 95% CI 1.42 to 2.76).                                                                 |
| Battie et al. 1995     | Job code (1–4), total occupational lifting (day), mean time working twisted/bent, mean time sitting at work, occupation driving (hr lifetime) | Disc bulging (summary score for upper T12-L4 and lower lumbar spine L4-S1) | There was no association between occupational loading and disc bulging.                                                                                     |
| Hung et al. 2014       | Workers that carry heavy loads divided into low, intermediate and moderate lifting loads.      | Disc bulging, L4 L5 and L5S1                                            | There was a statistically significant difference in disc bulging between lifting categories for L2 L3 (OR = 3.8 (2.3 to 6.3)), L3 L4 (OR = 3.62-4 to 5.6), L4 L5 (OR = 3.1 (2.0 to 4.9) and (L5S1 (OR = 2.6 (1.7 to 4.0) when comparing the high load to the low load groups. |
| Luoma et al. 1998      | Drivers, carpenters and office workers                                                        | Disc bulging                                                              | RevMan: Carpenters were more likely to have posterior disc bulging at L3 L4 (OR = 2.73; 95% CI 1.12 to 6.64) and anterior bulging at L45 (OR = 2.86; 95% CI 1.05 to 7.79) when compared to the sedentary group. There was no difference for anterior disc bulging at L2 L3 (OR = 2.60 95% CI 0.74 to 9.22), L3 L4 (OR = 3.0 95% CI 0.86 to 10.41) and L5S1 (OR = 1.39 95% CI 0.49 to 3.92) or posterior disc bulging at L2 L3 (OR = 2.53 95% CI 0.60 to 10.69), L4 L5 (OR = 1.92 95% CI 0.89 to 4.16) and L5S1 (OR = 1.33 95% CI 0.95 to 1.87) |
| Schenk et al. 2006     | nurses and office workers                                                                     | Disc abnormalities (bulging, protrusion, extrusion, etc)                 | RevMan: There was no significant difference in disc bulging between groups. (OR = 1.33 95% CI 0.95 to 197)                                                                                         |
| Videman et al. 2006    | Job code (1–4), occupational driving, maximum weight lifted at work (kg)                      | Disc bulging                                                              | There was an association between occupational lifting and disc bulging (0.07 points/disc increase in disc height = 0.065)                                                                               |
| Modic changes          | Elfering et al. 2002                                                                         | Modic changes (summary score for all levels together)                    | Occupational loading was not associated Modic changes                                                                                                                                                            |
| Schmorl’s nodes        | Schmorl’s nodes                                                                             | Modic changes                                                             | There was a significant difference in the incidence of Modic changes according to the level of physical work. In total 8 of 54 (15%) of those with light physical work had Modic changes, 16 of 99 (26%) of those with moderate physical load and 23 of 57 (40%) of those with hard physical work had modic changes |
| Endplate abnormalities | Friedoer et al. 1984                                                                        | Schmorl’s nodes                                                           | RevMan: There was no difference in Modic changes between groups. (OR = 0.91 95% CI 0.52 to 1.58),                                                                                                             |
|                       |                                                                                             | Endplate abnormalities                                                     | There was no association between lifting and the spine outcomes evaluated.                                                                                                                                      |
| Study           | Type of loading or exposure                                                                 | Outcomes                          | Study results and RevMan analysis                                                                                                                                 |

Fig. 2 Disc degeneration (signal intensity) forest plots for each spinal level, L1-S1
The results do suggest that occupations with greater physical loading are associated with modestly greater spine degeneration although differences in loading conditions and outcomes between studies make it difficult to draw strong, specific conclusions. This is especially true given that positive results were inconsistently found at different spinal levels and for different outcomes. Thus, it remains difficult to draw conclusions about which type of loading may negatively affect which type of degenerative or structural findings. Additionally, different imaging methods were used (e.g. MRI, CTScans and x-rays) and different methods to assess spine degeneration make it difficult to draw conclusions.

Limitations of the review are primarily related to the heterogeneity of the studies included. There was a wide range of types of occupational loading studied and a wide range of outcomes evaluated. Thus, although odds ratios were presented in the original manuscripts for most of the studies, it was not possible to pool the great majority of results and the findings of the review, therefore, were presented qualitatively. Finally, the poor methodological quality of some of the studies, with only a small portion assessing degeneration longitudinally, limits interpretation regarding the progression of spine degeneration.

Future research should focus on more longitudinal studies, where the development of spinal degeneration can be followed over time, with an adequate follow-up period to allow for structural changes to occur. Monozygotic twin studies should be considered, given the strength of twin study designs in minimizing possible confounding. Furthermore, individual loading exposures should be taken in consideration, especially as the activities and loading involved in any one profession can vary significantly. More specifically, the type and magnitude of loading should be depicted and evaluated in greater detail. Finally, with the advance of imaging techniques and measurement procedures, a wide variety of measures of spinal degeneration and pathology has resulted. Guidelines for measurement and better standardization of spine imaging phenotypes are needed to allow study comparisons and pooling of data to facilitate interpretation of the collective body of related research.

**Conclusion**

The results of this study suggest that there is moderate grade evidence of an association between occupational loading and disc degeneration in terms of signal intensity (disc degeneration). There is low or very low-quality grade evidence between loading and disc height, disc bulging, osteophytes, Modic changes, Schmorl’s nodes and other endplate abnormalities. While there seems to be a modest association between heavy occupational loading and spinal degenerative findings, the limitations of the results found in this review provide a weak foundation for practical applications and related health policies.
