(December 24, 2021)

We compute the full Lyapunov spectra for a hard-disk fluid under temperature gradient and shear. The system is thermalized by deterministic and time-reversible scattering at the boundary. This thermostating mechanism allows for energy fluctuations around a mean value which is reflected by only two vanishing Lyapunov exponents in equilibrium and nonequilibrium. The Lyapunov exponents are calculated with a recently developed formalism for systems with elastic hard collisions. In a nonequilibrium steady state the average phase-space volume is contracted onto a fractal attractor leading to a negative sum of Lyapunov exponents. Since the system is driven inhomogeneously we do not expect the conjugate pairing rule to hold which is confirmed numerically.

I. INTRODUCTION

Transport of energy and momentum is a central problem in nonequilibrium statistical mechanics, but so far most of our knowledge is confined to the macroscopic level. There is still a long way to go when it comes to understanding this phenomena in microscopic terms although significant progress has been made during the last years, with help from dynamical systems theory and computer simulations. In general, external forces are needed to drive a system out of equilibrium, but in order to prepare a nonequilibrium steady state the redundant energy has to be removed thus preventing the system from heating up indefinitely. One way out is the introduction of thermostating mechanisms [1–6]. Both stochastic [7–14] and deterministic/time-reversible thermostats are in use, the latter having been introduced to remain close to Hamiltonian dynamics.

Recently, an alternative thermostating mechanism [15–17] acting via deterministic time-reversible boundary-scattering has been applied on a hard disk fluid to model heat and shear flow nonequilibrium steady states [18]. The calculated transport coefficients have been found to be in agreement with the theoretical values obtained from kinetic theory, but only for special cases and in the thermodynamic limit the conjectured identity between exponential phase-space contraction and entropy production rate holds. In the present paper we investigate further the dynamical properties of this system by computing the full Lyapunov spectra and related quantities like the Kaplan-Yorke dimension or the Kolmogorov-Sinai entropy. In Sec. II we briefly recapitulate the model and its thermostating mechanism and Sec. III serves to outline the method used for computing the Lyapunov exponents [19,20]. The results are presented in Sec. IV and conclusions are drawn in Sec. V.

II. MODEL

Consider a two-dimensional system of hard disks confined in a square box of length $L$ with periodic boundary conditions along the x-axis, i.e., the left and right sides at $x = \pm L/2$ are identified. The $N$ disks interact among themselves via elastic hard collisions, thus the bulk dynamics is purely conservative. In the following and in all the numerical computations we use reduced units by setting the particle mass $m$, the disk diameter $\sigma$ and the Boltzmann constant $k_B$ equal to one. Now, denote with $p^t_x$, $p^t_y$ and with $p^f_x$, $p^f_y$ the tangential and normal momentum of a disk before and after a collision with the wall. Then the scattering prescription is given as [18]

\[
(p^f_x, p^f_y) = \begin{cases}
\mathcal{T}^{-1} \circ \mathcal{M} \circ \mathcal{T} (p^t_x, p^t_y), & p^t_x \geq 0 \\
\Pi \circ \mathcal{T}^{-1} \circ \mathcal{M}^{-1} \circ \mathcal{T} (p^t_x, p^t_y), & p^t_x < 0,
\end{cases}
\]

(1)

where $\mathcal{T} : [0, \infty) \times [0, \infty) \to [0, 1] \times [0, 1]$ is the invertible map

\[
(\zeta, \xi) = \mathcal{T} (p_x, p_y) = \left( \text{erf} \left( |p_x| / \sqrt{2}T \right), \exp \left( -p^2_y / 2T \right) \right)
\]

(2)
and $M : [0, 1] \times [0, 1] \rightarrow [0, 1] \times [0, 1]$ is a two-dimensional, invertible, phase-space conserving chaotic map to be specified later. $\Pi(p_x, p_y) = (p_x, -p_y)$ only serves to produce the right sign for the backward scattering. The parameter $T$ plays the role of a temperature \cite{13, 18}. Note that the colliding disk retains its tangential direction and that the scattering is reversible by construction.

So far, the model has only been defined in equilibrium. In order to drive the system into a nonequilibrium steady state (NSS) the collision rule only has to be modified appropriately, which will be done in Sec. \cite{13} (see also \cite{8}).

### III. METHOD

Like all hard disk systems our model is chaotic in the sense that two nearby phase space trajectories diverge exponentially with time. This is mainly due to the dispersing action of the hard disk collisions in the bulk, but especially for small particle numbers we also expect a contribution to this divergence due the chaotic nature of our scattering mechanism. The average logarithmic divergence rate in phase space are described by the so-called Lyapunov exponents $\lambda_i$. Denote by $\Gamma = \{q_1, q_2, \ldots, q_N, p_1, p_2, \ldots, p_N\}$ the 4N dimensional phase space vector for $N$ disks. Then, the time evolution

$$\Gamma(0) = \Phi^t[\Gamma(0)]$$

of an initial state $\Gamma(0)$ consists of a smooth streaming which is interrupted by particle-particle and particle-wall collisions. Next, consider a satellite trajectory $\Gamma_s(t)$ initially displaced from the reference trajectory by an infinitesimal vector $\delta \Gamma(0)$. In a chaotic system $|\delta \Gamma(0)|$ is growing on average exponentially, thus rendering the system unpredictable for long times. Then there exists a complete set of linear-independent initial vectors $\{\delta \Gamma_i(0) : i = 1, \ldots, 4N\}$ and Lyapunov exponents defined as \cite{21}

$$\lambda_i = \lim_{t \rightarrow \infty} \frac{1}{t} \ln \left| \frac{\delta \Gamma_i(t)}{\delta \Gamma_i(0)} \right|.$$  \hspace{1cm} (4)

The $\lambda_i$, which we order according to $\lambda_1 \geq \lambda_2 \geq \ldots \geq \lambda_{4N}$, are independent of the coordinate system and the metric. The whole set of Lyapunov exponents is referred to as the Lyapunov spectrum.

In Hamiltonian systems the Lyapunov exponents appear in pairs summing up to zero, $\lambda_i + \lambda_{4N-i+1} = 0$ for $i = 1, \ldots, 2N$, due to the symplectic nature of the equations of motion. In a continuous dynamical system one Lyapunov exponent associated with the direction of the phase flow vanishes. Moreover, each conserved quantity leads to an additional vanishing Lyapunov exponent. The symmetry found in symplectic dynamical systems is lost when the system is driven to a nonequilibrium stationary state. However, for homogeneous driving the symmetry is replaced by the so-called conjugate pairing rule \cite{22} saying that after excluding the vanishing exponents associated with the flow direction and the conservation of energy the remaining pairs, i.e. $\{\lambda_1, \lambda_{4N}\}$, $\{\lambda_2, \lambda_{4N-1}\}$, and so on, each sum up to the same negative value $C$. For inhomogeneously driven systems such as ours or the Chernov-Lebowitz shear flow model \cite{11, 12, 20}, however, the symmetry is lost and no pairing rules exist.

As can be seen from Eqs.\hspace{1cm} (3) the phase space volume is in general changed during each disk-wall collision. In equilibrium this averages up to zero, whereas in NSS the average phase space contraction rate is negative and is given by the sum of all Lyapunov exponents. Consequently, the phase volume shrinks continuously in NSS and and the phase-space distribution collapses onto a multifractal strange attractor. The fractal dimension of this strange attractor can be estimated with the conjecture of Kaplan-Yorke \cite{22},

$$D_{KY} = n + \frac{\sum_{i=1}^n \lambda_i}{|\lambda_{n+1}|}$$

where $n$ is the largest integer for which $\sum_{i=1}^n \lambda_i \geq 0$. $D_{KY}$ is the dimension of a phase space object which neither shrinks nor grows and for which the natural measure is conserved by the flow.

For the calculation of the full Lyapunov spectrum we use a method worked out by Dellago et al. \cite{14, 20} which is actually a generalization of the algorithm of Benettin et al. \cite{24} for smooth dynamical systems. The latter follows the time evolution of a reference trajectory and of a complement set of tangent vectors by solving the original and the linearized equations of motion, respectively. Periodic reorthonormalization prevents the tangent vectors from collapsing all into the direction of fastest growth. Averaging the logarithmic expansion and contraction rates of the tangent vectors then yields the Lyapunov exponents. For a hard disk system the free streaming is interrupted by impulsive collisions, either with another particle or the boundary. This certainly affects both the trajectory and the tangent space and has to be included in the calculation. The free streaming and the particle-particle collisions in the
bulk have been treated in Section III-D of reference [19], where the same notation was used as in the present work. We refer to Eqs. (39)-(42) and Eqs. (68)-(73) of this article for explicit expressions of the particle-particle collision rules in phase space and tangent space, respectively. It remains to consider the particle-wall collisions and the following lines are formulated in parallel to the respective treatment of Dellago and Posch for the Chernov-Lebowitz model [20]. In fact, the only difference lies in the 'scattering matrix' and its derivatives.

If particle $k$ collides with the walls its position remains unchanged whereas its momentum is changed according to the scattering rules Eq. (1). The collision map $\Gamma^f = M(\Gamma^i)$ in phase space becomes

$$q_j^f = q_j^i \quad \text{for} \quad j = 1, \ldots, N$$

$$p_j^f = p_j^i \quad \text{for} \quad j \neq k$$

$$p_k^f = C^+(p_k^i), \quad \text{for} \quad p_k^i \geq 0$$

$$p_k^f = C^-(p_k^i), \quad \text{for} \quad p_k^i < 0$$

using the abbreviations $C^+ = T^{-1} \circ M \circ T$ for the forward scattering and $C^- = \Pi \circ T^{-1} \circ M^{-1} \circ T$ for the backward scattering (Eq. (1)).

In order to obtain the corresponding transformation for the tangent space vector $\delta \Gamma$ at a particle-wall collision we assume that the collision takes place at phase point $\Gamma$ at time $\tau_c$. Then the satellite trajectory, displaced by the infinitesimal vector $\delta \Gamma$, collides at a different phase point $\Gamma + \delta \Gamma_c$ at a different time $\tau_c + \delta \tau_c$. A linear approximation in phase space and time yields [19]

$$\delta \Gamma^f = \frac{\partial M}{\partial \Gamma} \cdot \delta \Gamma^i + \left[ \frac{\partial M}{\partial \Gamma} \cdot (\Gamma - F(M(\Gamma^i))) \right] \delta \tau_c$$

where $F$ is the right hand side of the equation of motion during the free streaming [19], and $\partial M/\partial \Gamma$ is the matrix of the derivatives of the full collision map with respect to the phase-space coordinates. Obviously, the delay time $\delta \tau_c$ is a function of the phase point $\Gamma^i$ and of the tangent vector $\delta \Gamma^i$. For a disk-wall collision of the $k$th particle the delay time $\delta \tau_c$ is given by

$$\delta \tau_c = -\frac{\langle \delta q_k \cdot n \rangle}{\langle p_k \cdot m \cdot n \rangle}.$$  

Here, $n$ is the normal vector of the wall pointing into the simulation box. Since the scattering rules Eq. (1) for the momentum components is independent of the position of the particle, the matrix $\partial M/\partial \Gamma$ has the form

$$\frac{\partial M}{\partial \Gamma} = \begin{pmatrix} 1 & 0 \\ 0 & \frac{\partial C^\pm(p^i)}{\partial (p^i)} \end{pmatrix}$$

where $1$ and $0$ are the $2N \times 2N$ unit and zero matrices, respectively. $\partial C^\pm(p^i)/\partial (p^i)$ is the matrix of the derivatives of the outgoing momenta with respect to the incoming momenta and only the components of the colliding particle $k$ are different from zero. From Eq. (12) the following transformation rules for the tangent vectors can be deduced:

$$\delta q_j^f = \delta q_j^i \quad \text{for} \quad j \neq k$$

$$\delta p_j^f = \delta p_j^i \quad \text{for} \quad j \neq k$$

$$\delta q_k^f = \delta q_k^i - (p_k^i - p_k^i) \delta \tau_c$$

$$\delta p_k^f = \frac{\partial C^\pm(p_k^i)}{\partial (p_k^i)} \cdot \delta p_k^i.$$  

Omitting for notational convenience the index $k$ indicating the colliding particle we obtain from Eq. (1) the following expressions for the $2 \times 2$ matrix $(\partial C^\pm(p_k^i)/\partial (p_k^i))_{\alpha \beta} = \partial p_{\alpha}^f / \partial p_{\beta}^i$, $\alpha, \beta \in \{x, y\}$:

$$\frac{\partial p_{\alpha}^f}{\partial p_{\beta}^i} = (D_M)_{11} \exp \left[ \frac{((p_{\alpha}^i)^2 - (p_{\beta}^i)^2)/(2T)}{} \right] , \quad \frac{\partial p_{\alpha}^f}{\partial p_{\beta}^i} = - (D_M)_{12} \frac{\pi p_{\beta}^i}{\sqrt{2T}} \exp \left[ \frac{((p_{\alpha}^i)^2 - (p_{\beta}^i)^2)/(2T)}{} \right]$$

$$\frac{\partial p_{\alpha}^f}{\partial p_{\beta}^i} = - (D_M)_{21} \frac{\sqrt{2T}}{\pi p_{\beta}^i} \exp \left[ \frac{((p_{\alpha}^i)^2 - (p_{\beta}^i)^2)/(2T)}{} \right] , \quad \frac{\partial p_{\alpha}^f}{\partial p_{\beta}^i} = (D_M)_{22} \frac{p_{\beta}^i}{p_{\alpha}^i} \exp \left[ \frac{((p_{\alpha}^i)^2 - (p_{\beta}^i)^2)/(2T)}{} \right] ,$$

for $p_{\beta}^i > 0$.  

3
Here, $\mathbf{DM}$ denotes the matrix of the derivatives of the chaotic map $\mathcal{M}$. Eqs. (17,18) are stated for positive tangential velocities, for negative tangential velocities $\mathcal{M}$ has only to be replaced by $\mathcal{M}^{-1}$, see Eq. (1).

Combining the free streaming with the transformation for the disk-disk and the disk-wall collisions, one is now able to follow the exact time evolution of the trajectory and of the tangent-space vector.

IV. RESULTS

Using the algorithm outlined in the previous section we are now able to calculate the full Lyapunov spectrum for our hard disk model with deterministic scattering at the boundary. As already mentioned we use reduced units by setting the particle mass $m$, the disk diameter $\sigma$ and the Boltzmann constant $k_B$ equal to unity. We define the number density by $\bar{\rho} = N/L^2$. For simulation we use a collision-to-collision approach and neighbor lists. For an initial configuration the centers of the disks are positioned on a triangular lattice and the momenta are chosen from a Gaussian with zero mean. The total momentum is then set to zero and the momenta are rescaled to obtain the total kinetic energy $E_{\text{kin}} = N(T_u + T_d)/2$, $T_u$ and $T_d$ being the imposed 'parametrical' temperatures of the upper and the lower wall, respectively.

A. Equilibrium

We now set both wall temperatures $T_u$, $T_d$ equal to one and compute the full Lyapunov spectra for a four-particle system at number density $\bar{\rho} = 0.2$ using three different chaotic maps:

$$\mathcal{M}_B(\zeta, \xi) = (k\zeta, \xi/k) \pmod{1}, \quad \text{(baker map)}$$

$$\mathcal{M}_C(\zeta, \xi) = ((k + 1)\zeta + \xi, k\zeta + \xi) \pmod{1}, \quad \text{(cat map)}$$

and

$$\mathcal{M}_S: \begin{cases} 
\zeta' = \xi - \frac{k}{2\pi} \sin(2\pi \zeta), \\
\xi' = \zeta + \xi 
\end{cases} \pmod{1}, \quad \text{(standard map)}$$

with $0 \leq \zeta, \xi \leq 1$. $k \in 2N$ is a parameter controlling the chaoticity of the map, i.e. the magnitude of the Lyapunov exponents.

The resulting spectra are shown in Fig. 1 where we have also plotted the Lyapunov spectrum for elastic reflection as reference. To emphasize the conjugate pairs, the Lyapunov exponents are ordered as $\{\lambda_{2N-i+1}, \lambda_{2N+i}\}$, with $i = 1, \ldots, 2N$. Errors are estimated as in [20] from the convergence of the exponents as a function of simulation time such that the time-dependent exponents did not deviate more than $\pm \Delta \lambda$ from their mean values during the second half of the simulation run. For high accuracy more than $10^7$ disk-disk collisions and more than $5 \cdot 10^6$ disk-wall were simulated yielding errors less than $\pm 0.001$ for the exponents and less than $\pm 0.002$ for the pair sums. In the case of elastic reflection three Lyapunov exponents vanish. One exponent vanishes due to the neutral expansion behavior in the direction of the flow, a second due to the conservation of kinetic energy. The third exponent is zero due to the translational invariance of the system in the $x$-direction [20]. The fourth vanishing exponent then verifies the pairing rule. For a hard disk system thermostated by deterministic scattering only two Lyapunov exponents vanish. The kinetic energy is now allowed to fluctuate around a mean value, so only the neutral expansion and the translational invariance remain. As we expect the maximum Lyapunov exponent increases with increasing chaoticity of the map, i.e. when going from a baker map ($k = 2$) to a cat map ($k = 2$) to a standard map ($k = 100$) (Results not plotted here show a similar behavior when $k$ is increased for a given map.). The pairing rule for these models is satisfied with an error of $\pm 0.002$ in the pair sums. At this point we add a remark which might seem at first purely technical. For all simulations we used a symmetrical configuration, i.e. Eq. (1) is used for the upper wall whereas $\mathcal{M}$ and $\mathcal{M}^{-1}$ are interchanged in Eq. (1) for the lower wall. Using the same scattering rules for both walls results in an asymmetry and eventually in an asymmetric Lyapunov spectrum even in equilibrium violating the pairing rule.

B. NSS

We move on to the nonequilibrium stationary state and turn first to the case of an imposed temperature gradient by the walls. Since in the thermodynamic limit the Lyapunov spectrum is mainly determined by the bulk behavior
we use in the following only a cat map with \( k = 2 \) as chaotic map \( \mathcal{M} \). In order to determine the macroscopic state of the system the velocity and density profiles of the bulk are measured as well as the temperatures and velocities of the walls. Wall velocities are defined as the mean tangential velocity of the incoming and outgoing particles. Wall temperatures are defined as mean temperature of the incoming and outgoing fluxes, \( \mathbf{T} = (\mathbf{T}_1 + \mathbf{T}_o)/2 \), with \( \mathbf{T}_{i/o} = \left(\langle (v_x - \langle v_x \rangle_x) \rangle_x + [v_y]_y \right)/2 \) where \( \langle \rangle_x \) and \([\ ]_y \) represent an average over the density \( \rho(v_x) \) and the flux \( \Phi \) to and from the wall, respectively (see also [18]).

1. Heat flow

Again, we first investigate a small system with four particles at \( \bar{T} = 0.2 \) with high accuracy. In order to impose a temperature difference on the system we only have to choose two different parametrical temperatures \( T_u, T_d \) (see Eq.(2) and [18]). Note that this also affects the derivatives of the collision matrix (Eqs. (17, 18)). Figure 2 shows the spectra for this system under a temperature gradient, the numbers denoting the parametrical temperatures \( T_u/d \) of the upper and the lower wall. In NSS the sum of the Lyapunov exponents is negative and exactly equal to the phase space contraction rate. \( T_u - T_d = 1 - 3 \) results in \( \sum \lambda_l = -1.029 \) and \( T_u - T_d = 1 - 5 \) in \( \sum \lambda_l = -2.703 \). We find again two vanishing Lyapunov exponents but with increasing temperature difference all nonzero exponents also increase in magnitude, the negative ones certainly stronger to yield an overall negative sum. The pair sums are also shown and, as we expect, the driving shifts the sums towards negative values thus destroying the symmetry. The deviations from the pairing rule are particularly strong for pairs with large \( i \). Figure 3 shows the results for a 36-particle system under the same setting. At least \( 2 \cdot 10^6 \) disk-disk collisions and \( 2 \cdot 10^7 \) disk-wall collisions have been simulated in each run. The spectra are plotted as connected lines only for graphical reasons, it is understood that the exponents are defined for integer \( i \) only. The change in the Lyapunov spectrum under thermal driving are similar to the four-particle system. Increasing the density from \( \bar{T} = 0.2 \) to \( \bar{T} = 0.6 \) results in a larger magnitude of all nonzero exponents due to the higher collision rate. The Kaplan-Yorke dimension \( D_{KY} \) [Fig. 4] is decreasing for increasing temperature gradient, with a larger dimensionality loss \( \Delta D_{KY} \) for higher densities than for lower densities at given \( \Delta T \). As can immediately be guessed from the positive branch of the spectra thermal driving also results in an increasing Kolmogorov-Sinai entropy \( h_{KS} \) [Fig. 5], defined as the sum over all positive exponents,

\[
h_{KS} = \sum_{\{\lambda_l>0\}} \lambda_l,
\]

with increasing temperature gradient. So, as we expect from thermodynamics, thermal driving reduces the ordering of the system. Higher collision rates at higher densities lead to more viscous heating in the bulk and eventually to an increasing disorder (\( h_{KS} \)) of the system. The second, lower data point at \( \Delta T = 0 \) shows \( h_{KS}/N \) for elastic reflection as reference.

2. Shear flow

One way to model moving walls is to add some tangential momentum \( d \) to \( p_x \) before and after the collision of a particle with the boundary (model I in [18]),

\[
(p'_x, p'_y) = \begin{cases} 
\mathcal{S}_d \circ \mathcal{C}^+ \circ \mathcal{S}_d(p_x^i, p_y^i), & p_x^i \geq -d \\
\mathcal{S}_d \circ \mathcal{C}^- \circ \mathcal{S}_d(p_x^i, p_y^i), & p_x^i < -d,
\end{cases}
\]

(23)

with

\[
\mathcal{S}_d(p_x^i, p_y^i) = (p_x^i + d, p_y^i).
\]

(24)

In order to impose shear the shift \( d \) has only to be chosen with different signs for the upper and the lower wall. Note that these scattering rules are time reversible. Certainly, the drift also affects the derivatives of the collision matrix, Eqs. (17, 18), where \( p_x^i \) goes to \( p_x^i + d \) and \( p_x^i \) to \( p_x^i - d \). Figure 6 shows the full Lyapunov spectra and the pair sums for a 36-particle system at \( \bar{T} = 0.6 \) under shear while keeping \( T_u = T_d = 1 \) fixed. The negative exponents increase in magnitude whereas the positive branch changes very little. Before we take a closer look at the Kaplan-Yorke dimension and the Kolmogorov-Sinai entropy let us investigate another scattering rule (model III in [18]) which also models moving walls:
\( (p'_x, p'_y) = T^{-1}_s \circ \mathcal{M} \circ T_s(p_x, p_y) \) \hspace{1cm} (25)

with

\[
T_s(p_x, p_y) = \left( \frac{\text{erf} \left[ (p_x - d)/\sqrt{2T} \right] + 1}{2}, \exp\left( -p_y^2/2T \right) \right)
\] \hspace{1cm} (26)

Model III is still deterministic but no longer time reversible and only using this shear model a (numerical) equality between phase space contraction rate and entropy production was found in [18]. Note that \( p'_x \) changes now to \( p'_x - d \) and \( p'_y \) to \( p'_y - d \) in Eqs. (17,18). Figure 6 shows the corresponding Lyapunov spectra for a 36-particle system at \( T = 0.6 \) under shear, but in contrast to model I the Lyapunov exponents of both the positive and the negative branch now increase in magnitude with increasing shear rate \( \gamma \). For comparison the Lyapunov spectrum for the Chernov-Lebowitz model is also plotted, with \( E_{kin}/N \) and \( \gamma \) equal to values obtained with model III at \( d = 1.5 \). \( D_{KY} \) for both models is compared in Fig. 7(a) and we see that the dimensionality loss with increasing shear rate \( \gamma \) is stronger for model I than for model III. The graph of \( h_{KS} \) plotted for both models in Fig. 7(b) asks for more explanation. Firstly, the overall behavior of \( h_{KS} \) is increasing with larger \( \gamma \), which seems to be the opposite of the observation made for the Chernov-Lebowitz shear model in [20]. But there the total kinetic energy is kept constant for all shear rates whereas here both models try to fix the wall temperature. Increasing shear results in an increasing viscous heat production in the bulk which is reflected by a larger mean kinetic energy per particle [Fig. 8(a)]. Hence, the loss in \( h_{KS} \) due to the ordering introduced by the shear is more than compensated by an increase of disorder due to a higher temperature in the bulk. Secondly, the only minor changes in the positive branch of the Lyapunov spectra for model I under shear yield an initially almost constant or even decreasing Kolmogorov-Sinai entropy. This, and the even more puzzling behavior of the wall temperature [Fig. 8(b)] can be explained by the fact that model I does not produce a Gaussian outgoing flux after the scattering. We found in [18] that model I leads to an outgoing distribution with strong discontinuities in NSS whereas model III yields proper outgoing Gaussians. For comparison we have also computed \( D_{KY} \) and \( h_{KS} \) for the Chernov-Lebowitz model when it is approximately in the same macroscopic state as model III, i.e. we set the Chernov-Lebowitz system on the same kinetic energy shell and tried to find the appropriate shear parameter which results in the same shear rate. The Kaplan-Yorke dimension seems to be almost identical with that of model I, Fig. 7(a), and furthermore, the Kolmogorov-Sinai entropy now also increases with larger shear rate, only differing by a constant with the one obtained from model III, Fig. 7(b). This offset, depending on the special type of chaotic map chosen, originates from the fluctuating character of the model and should vanish in the thermodynamic limit.

V. CONCLUSION

We have calculated the full Lyapunov spectrum for a hard-disk fluid in equilibrium and nonequilibrium steady states thermostated by deterministic scattering. Since the model allows for fluctuations around a mean total energy only two vanishing Lyapunov exponents are found in both equilibrium and nonequilibrium states. In nonequilibrium the system is dissipative with a mean phase-space contraction rate smaller than zero. The magnitude of the Lyapunov exponents increases with increasing temperature gradient or shear rate, with a stronger increase for the negative branch. Thus both heat and shear flow situations result in a decreasing Kaplan-Yorke dimension and an increasing Kolmogorov-Sinai entropy with stronger nonequilibrium. Due to the inhomogeneous driving at the boundary the pairing rule does not hold. We did not verify the relation between Lyapunov exponents and transport coefficients (as e.g. in [22]) since in absence of a pairing rule this would be equivalent to checking the relation between phase space contraction and entropy production rates, where the latter has been done in [18]. The main difference of our shear flow model III and the Chernov-Lebowitz shear flow model is the fact that in the latter the total kinetic energy is fixed whereas our models tries to fix the wall temperature. A direct comparison of both models reveals that they yield identical Kaplan-Yorke dimensions and only differ by a constant in the Kolmogorov-Sinai entropy, which vanishes in the thermodynamic limit.

ACKNOWLEDGMENTS

Special thanks go to Ch. Dellago for providing and explaining the original code used to compute the Lyapunov spectra and for helping to interpret the results. Furthermore, the author likes to thank O. Agullo for his technical support and R. Klages for pointing out relevant literature and for giving valuables advice. This work is supported, in
part, by the Interuniversity Attraction Pole program of the Belgian Federal Office of Scientific, Technical and Cultural Affairs and by the Training and Mobility Program of the European Commission.

FIG. 1. Lyapunov spectra for a four particle system with density $\pi = 0.2$ in equilibrium. The solid line shows the spectrum for elastic reflection, i.e. the identity map is used instead of a chaotic one. The other spectra are obtained by using a baker map with $k = 2$, a cat map with $k = 2$ and a standard map with $k = 100$, see Eqs.(19)-(21).

FIG. 2. Lyapunov spectra for a four particle system at density $\pi = 0.2$ in NSS. The imposed temperatures for the upper and the lower wall are indicated by the numbers. The respective pair sums (scaled by a factor 1/2 for graphical reasons) are also plotted near the middle line.
FIG. 3. Full Lyapunov spectra for a 36-particle system under an imposed temperature gradient at number densities $\bar{n} = 0.2$ and $\bar{n} = 0.6$. The numbers indicate the parametrical temperatures $T_u$, $T_d$. The respective pair sums (scaled by a factor $1/2$ for graphical reasons) are also plotted near the middle line.
FIG. 4. The Kaplan-Yorke dimension $D_{KY}$ and the Kolmogorov-Sinai entropy $h_{KS}$ per particle for a 36-particle system under a temperature gradient at number densities $\bar{n} = 0.2$ and $\bar{n} = 0.6$. $\Delta T$ denotes the measured temperature difference between the upper and the lower wall. The second, lower data point at $\Delta T = 0$ gives $h_{KS}/N$ for elastic reflection as reference.
FIG. 5. Full Lyapunov spectra for a 36-particle system under shear at number density $\bar{n} = 0.6$, model I.

FIG. 6. Full Lyapunov spectra for a 36-particle system under shear at number density $\bar{n} = 0.6$, model III. The spectrum for the Chernov-Lebowitz model results from a simulation with the same mean kinetic energy per particle and approximately the same shear rate as model III with $T_u = T_d = 1.0$ and $d = 1.5$. 

11
FIG. 7. The Kaplan-Yorke dimension $D_{KY}$ and the Kolmogorov-Sinai entropy $h_{KS}$ per particle for a 36-particle system under shear at number density $\tau = 0.6$ as a function of the shear rate $\gamma$ (model I, model III and Chernov-Lebowitz model).
FIG. 8. Kinetic energy per particle and measured wall temperature for a 36-particle system under shear at number density $\tau = 0.6$ as a function of the shear rate $\gamma$ (model I and model III).
