Charged and strange hadron elliptic flow in Cu + Cu collisions at $\sqrt{s_{NN}} = 62.4$ and 200 GeV
We present the results of an elliptic flow, $v_2$, analysis of Cu + Cu collisions recorded with the solenoidal tracker detector (STAR) at the BNL Relativistic Heavy Ion Collider at $\sqrt{s_{NN}} = 62.4$ and 200 GeV. Elliptic flow as a function of transverse momentum, $v_2(p_T)$, is reported for different collision centralities for charged hadrons $h^\pm$ and strangeness-containing hadrons $K_0^0$, $\Lambda$, $\Xi$, and $\phi$ in the midrapidity region $|\eta| < 1$.0. Significant reduction in systematic uncertainty of the measurement due to nonflow effects has been achieved by correlating particles at midrapidity, $|\eta| < 1.0$, with those at forward rapidity, 2.5 < $|\eta|$ < 4.0. We also present azimuthal correlations in p + p collisions at $\sqrt{s} = 200$ GeV to help in estimating nonflow effects. To study the system-size dependence of elliptic flow, we present a detailed comparison with previously published results from Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV. We observe that $v_2(p_T)$ of strange hadrons has similar scaling properties as were first observed in Au + Au collisions, that is, (i) at low transverse momenta, $p_T < 2$ GeV/c, $v_2$ scales with transverse kinetic
energy, \( m_T - m \), and (ii) at intermediate \( p_T \), \( 2 < p_T < 4 \text{ GeV}/c \), it scales with the number of constituent quarks, \( n_q \). We have found that ideal hydrodynamic calculations fail to reproduce the centrality dependence of \( v_2(p_T) \) for \( K^0 \), \( \Lambda \), and \( \Sigma \). Eccentricity scaled \( v_2 \) values, \( v_2/\epsilon \), are larger in more central collisions, suggesting stronger collective flow develops in more central collisions. The comparison with Au + Au collisions, which go further in density, shows that \( v_2/\epsilon \) depends on the system size, that is, the number of participants \( N_{\text{part}} \). This indicates that the ideal hydrodynamic limit is not reached in Cu + Cu collisions, presumably because the assumption of thermalization is not attained.

I. INTRODUCTION

At the early stages of relativistic heavy-ion collisions, a hot and dense, strongly interacting medium is created. The subsequent system evolution is determined by the nature of the medium. Experimentally, the dynamics of the system evolution has been studied by measuring the azimuthal anisotropy of the particle production relative to the reaction plane \([1–3]\). The centrality of the collision, defined by the transverse distance between the centers of the colliding nuclei called the impact parameter, results in an “almond-shaped” overlap region that is spatially azimuthal anisotropic. It is generally assumed that the initial spatial anisotropy in the system is converted into momentum-space anisotropy through rescatterings \([4,5]\). The elliptic flow, \( v_2 \), is the second harmonic coefficient of a Fourier expansion of the final momentum-space azimuthal anisotropy. Because of the self-quenching effect, it provides information about the dynamics at the early stage of the collisions \([6–8]\). Elliptic flow can provide information about the pressure gradients, the effective degrees of freedom, the degree of thermalization, and the equation of state of the matter created at the early stage. Thus, the centrality and system-size dependence of elliptic flow at different beam energies can be used to study the properties of the matter created in heavy-ion collisions \([6]\).

Recently, two important insights have been obtained from the experimental results on \( v_2 \) as a function of transverse momentum, \( p_T \), in Au + Au collisions at the BNL Relativistic Heavy Ion Collider (RHIC). First, in the low \( p_T \) region, \( p_T < 2 \text{ GeV}/c \), the hadron mass hierarchy predicted by ideal hadron hydrodynamics is observed for identified hadrons \( \pi^\pm, K^\pm, p, \Lambda, \Sigma \) \([9–13]\). Even the \( \phi \) and \( \Omega \), which are believed to have a reduced cross section for hadronic interactions \([14–19]\), are consistent with the mass ordering \([13,20,21]\). Second, in the intermediate \( p_T \) region, \( 2 < p_T < 4 \text{ GeV}/c \), \( v_2(p_T) \) follows a scaling depending on the number of constituent quarks within a given hadron, which can be explained via coalescence models \([13,20,22]\). Quark number scaling suggests that the system is in a partonic state and that the constituent quark degrees of freedom were relevant during the time \( v_2 \) was developed.

The STAR Collaboration’s first published article showed that elliptic flow at RHIC is unexpectedly large \([23]\), comparable to predictions of ideal hydrodynamic calculations \([7,24–26]\). This observation is among the evidence favoring the picture of a nearly perfect liquid \([27]\). With the assumption of thermalization, ideal hydrodynamic calculations predict that the \( v_2 \) divided by spatial eccentricity, \( \epsilon \), does not depend on the collision centrality \([28]\). The spatial eccentricity is defined by \([29]\)

\[
\epsilon = \frac{\langle y^2 - x^2 \rangle}{\langle y^2 + x^2 \rangle},
\]

where \( x \) and \( y \) are the spatial coordinates in the plane perpendicular to the collision axis. The angle brackets \( \langle \rangle \) denote an average weighted by the initial density. However, recent RHIC \( v_2/\epsilon \) data for charged hadrons \( h^\pm \) and strangeness-containing hadrons \( K^0_S, \phi, \Lambda, \Sigma \) show a trend to increase as a function of the particle density scaled by the system-size \([30,31]\), lacking the saturation indicated by ideal hydrodynamic calculations \([31]\). This monotonic increase is a feature of a class of model descriptions that conform to the low-density limit \([32]\). Whether the thermalization and ideal hydrodynamic limit are reached or not at RHIC is not conclusive. A transport model suggested in Ref. \([33]\) is constructed to link the low-density limit to the ideal hydrodynamic limit. In the microscopic transport picture, the ideal hydrodynamic limit is reached when the mean free path is very small or the cross section is very large. With this transport model approach, the degree of thermalization and the ideal hydrodynamic limit can be addressed \([34]\).

The previous results mainly focus on the centrality dependence of charged hadrons and identified hadrons \( v_2 \) in Au + Au collisions. Because the conditions in Au + Au collisions might not hold in smaller systems and at lower beam energies, the system-size and beam-energy dependence of identified hadron elliptic flow will shed light on the properties of partonic collectivity and quark degrees of freedom. Further, the study of \( v_2 \) in collisions of nuclei smaller than Au + Au will allow us to test the early thermalization hypothesis in Au + Au collisions. To date, there are only a few studies of an identified hadron \( v_2 \) in Cu + Cu collisions. In this article, we present the results on the azimuthal anisotropy parameter \( v_2(p_T) \) of \( h^\pm, K^0_S, \Lambda, \Sigma, \) and \( \phi \) from \( \sqrt{s_{NN}} = 62.4 \) and 200 GeV Cu + Cu collisions. As a function of collision centrality, the scaling properties of \( v_2 \) with the transverse kinetic energy \( m_T - m \) and the number of constituent quarks \( n_q \) are reported. In the quantity \( m_T = \sqrt{p_T^2 + m^2} \), \( m \) denotes the rest mass of a given hadron. We also discuss system-size dependence in this article.

The rest of the article is organized in the following way: Section II summarizes the analysis details including data and centrality selections, particle identification and flow methods used for charged hadrons and identified hadrons.
In the following, we use $h^\pm$, $\Lambda$, and $\Xi$ to denote charged hadron, $\Lambda + \bar{\Lambda}$, and $\Xi^- + \Xi^0$, respectively. In Sec. III, we present measurements of $v_2$ for $h^\pm$ in Cu + Cu collisions from different analysis methods. Differences in $v_2$ are used to estimate the systematic error. Section IV presents the results and physics discussion of the scaling properties and system-size dependence along with ideal hydrodynamic calculations. Last, a summary is presented in Sec. V.

II. EXPERIMENTS AND ANALYSIS

A. Experiments and data sets

For this article, our data were collected from $\sqrt{s_{NN}} = 62.4$ and 200 GeV Cu + Cu collisions with the solenoidal tracker at RHIC (STAR) detector during the fifth RHIC run in 2005. In addition data from $\sqrt{s_{NN}} = 200$ GeV $p + p$ collisions in 2005 were used in the analysis of nonflow contributions. STAR’s main time projection chamber (TPC) [35] and two forward time projection chambers (FTPCs) [36] were used for particle tracking in the central region ($|\eta| < 1.0$) and forward regions ($2.5 < |\eta| < 4.0$), respectively. Both the TPC and FTPCs provide azimuthal acceptance over $2\pi$. Only those events that have the primary vertex position along the longitudinal beam direction ($V_z$) within 30 cm of the nominal collision point are selected for the analysis. This is done in order to have a more uniform detector performance within $|\eta| < 1.0$. The centrality definition, which is based on the raw charged particle TPC multiplicity with $|\eta| < 0.5$, is the same as that used previously [37]. After quality cuts, the number of the 60% most central events is about 24 million for 200 GeV Cu + Cu collisions and 10 million for 62.4 GeV Cu + Cu collisions. The results from more peripheral collisions are not presented because of trigger inefficiencies at low multiplicity.

The centrality was defined using the number of charged tracks with quality cuts similar to those in Ref. [31]. The 60% most central events for $v_2$ analysis of $h^\pm$ were divided into six centrality bins, each spanning an interval of 10% of the geometric cross section. For $v_2$ analysis of $K^0_S$ and $\Lambda$, centrality bins of 0%–20% and 20%–60% were used. To reduce the multiplicity fluctuations in wide centrality bins, we calculated $v_2$ in the 10% wide bins, then combined them using particle yield as the weight.

To select good tracks from primary collisions, charged particle tracks coming from the collision that transversed the TPC or FTPCs were selected by requiring the distance of closest approach to the primary vertex be less than 3 cm. Tracks used for $K^0_S$, $\Lambda$, and $\Xi$ reconstruction were not subject to this cut. We required that the TPC and FTPCs had a number of hits used for reconstruction of the tracks of the particles >15 and >5, respectively. For the TPC and FTPCs the ratio of the number of fit hits to maximum possible hits was >0.52. An additional transverse momentum cut ($0.15 < p_T < 2$ GeV/$c$) was applied to the charged tracks for the event plane determination.

B. Particle identification

We utilized the topology of decay as measured with the TPC inside the magnetic field to identify $K^0_S$, $\phi$, $\Lambda$ ($\bar{\Lambda}$), and $\Xi^-$ ($\Xi^- S$). We used the following decay channels: $K^0_S \rightarrow \pi^+ + \pi^-$, $\phi \rightarrow K^+ + K^-$, $\Lambda \rightarrow p + \pi^-$ ($\bar{\Lambda} \rightarrow \bar{p} + \pi^+$), and $\Xi^- \rightarrow \Lambda + \pi^- (\Xi^- S \rightarrow \Lambda + \pi^+)$. Similar to the previous analysis in Ref. [31], topological and kinematic cuts were applied to reduce the combinatorial backgrounds. Figure 1 shows the invariant mass distributions for (a) $K^0_S$, (b) $\phi$, (c) $\Lambda$, and (d) $\Xi$ for selected $p_T$ bins in $\sqrt{s_{NN}} = 200$ GeV Cu + Cu 60% most central collisions. The cuts used for Cu + Cu collisions are similar to those for Au + Au collisions in Ref. [31]. The combinatorial backgrounds were estimated from the fourth-order polynomial fits for $K^0_S$ and $\Lambda$ [31]. The invariant mass distribution for $\phi$ is after subtraction of combinatorial background estimated using event mixing [38]; the remaining combinatorial backgrounds were estimated by a first-order polynomial fit [20]. For $\Xi$, the background was estimated by rotating the transverse momentum of the daughter $\Lambda$ by 180°. This operation breaks the correlation between the $\Lambda$ and the other daughter particle. The resulting invariant mass distributions provide a good approximation of the true background distribution. The detailed description of the method can be found in Refs. [12,13].

C. Flow methods

Anisotropic flow, which is an anisotropy in the particle production relative to the reaction plane, results in correlations among particles and can be studied by the analysis of these correlations. At the same time these correlations are affected by other effects that are not related to the orientation of the reaction plane. Such are commonly referred to as nonflow, and are due, for example, to resonance decays and jet production. Different methods used to measure anisotropic flow are affected by nonflow effects in different ways and are used in this analysis to evaluate the systematic uncertainty of the measurements.

1. Event plane method with TPC event plane

The event plane method [2] uses the anisotropic flow itself to determine the event plane (the estimated reaction plane), which can be done for each harmonic. The second-harmonic flow vector, \( Q_2 \), of the event is constructed using the TPC tracks \( i \) in the event with their azimuthal angle, \( \phi_i \), according to Eqs. (2) and (3). To maximize the resolution of the flow effect, the weights \( w_i \) are set equal to \( p_T \) up to 2 GeV/c:

\[
Q_2 \cos(2\Psi_2) = Q_{2x} = \sum_i w_i \cos(2\phi_i), \quad (2)
\]

\[
Q_2 \sin(2\Psi_2) = Q_{2y} = \sum_i w_i \sin(2\phi_i) \quad (3)
\]

Elliptic flow is first calculated with respect to the event plane angle \( \Psi_2 \) as shown in Eq. (4), which is called the observed \( v_2 \). The angle brackets indicate an average over all particles in all events. However, tracks used for the \( v_2 \) calculation are excluded from the calculation of the flow vector to remove autocorrelation effects. Then the observed \( v_2 \) is corrected by the event plane resolution [the denominator in Eq. (5)] to obtain \( v_2 \) relative to the event plane:

\[
v_2^{\text{obs}} = \langle \cos[2(\phi - \Psi_2)] \rangle, \quad (4)
\]

\[
v_2 = \frac{v_2^{\text{obs}}}{\langle \cos[2(\Psi_2 - \Psi_2)] \rangle}. \quad (5)
\]

The results are denoted as \( v_2^{\text{TPC}} \) in the following.

Because the reaction plane is unknown, the denominator in Eq. (5) is still not calculable. As shown in Eq. (6), we estimate the event plane resolution by the correlations between the azimuthal angles of two subevent groups of tracks, called subevents A and B. In this analysis, we use two random subevents with equal numbers of particles. In Eq. (6), \( C \) is a constant calculated from the known multiplicity dependence of the resolution [2]:

\[
\langle \cos[2(\Psi_2 - \Psi_2)] \rangle = C \sqrt{\frac{\cos[2(\Psi_2^A - \Psi_2^B)]}{\sin^2(\Psi_2)}}. \quad (6)
\]

In the case of low resolution (\( \leq 0.2 \)), such as for the FTPC event plane, \( C \) approaches \( \sqrt{2} \).

The reaction plane azimuthal distribution should be isotropic in the laboratory frame. Thus, the event plane azimuthal distribution must be flat if the detectors have ideal acceptance. Because the detectors usually have nonuniform acceptance, a procedure for flattening the event plane distribution is necessary. For the event plane reconstructed from TPC tracks, the \( \phi \) weight method is an effective way to flatten the distribution. The \( \phi \) weights are generated by inverting the \( \phi \) distributions of detected tracks for a large event sample. The detector acceptance bias is removed by applying the \( \phi \) weight at the \( \phi \) of each track to that track. The \( \phi \) weights are folded into the weight \( w_i \) in Eqs. (2) and (3). Independent corrections were applied to each centrality selection in 10% increments and in two bins in the primary vertex position along the longitudinal beam direction (\( V_z \)). The corrections were done on a run-by-run basis (around 50k events).

2. Event plane method with FTPC event plane

The \( \eta \) gap between two FTPCs sitting at two sides of the collision in the forward regions can be used to reduce nonflow effects due to short-range correlations. The basic procedures are similar to those for the event plane method with the TPC event plane. There are three steps: estimate the event plane with FTPC tracks, calculate \( v_2 \) with respect to the event plane, and obtain the real \( v_2 \) by correction to the real reaction plane. Equations (2)–(6) can be applied, except that (i) the sums in Eqs. (2) and (3) go over FTPC tracks instead of TPC tracks and (ii) two subset groups of tracks are classified according to the sign of \( \eta \). The tracks with \(-4 < \eta < -2.5 \) and \( 2.5 < \eta < 4 \) are called east subevent and west subevent, respectively. Hence, the resolution in Eq. (6) is calculated by the correlation between the azimuthal angles \( \Psi_2^\text{east} \) and \( \Psi_2^\text{west} \). The average in Eq. (4) runs over the FTPC tracks as before. The result of this procedure is denoted as \( v_2^{\text{FTPC}} \).

Because of the serious loss of acceptance for FTPCs due to partially nonfunctioning readout electronics, the number of tracks detected by the best sector is about 6 times greater than that for the worst one. The result is that the \( \phi \) weight method is not enough to generate a flat event plane distribution. Thus, further small corrections are applied after \( \phi \) weight corrections using the shift method [39]. Equation (7) shows the formula for the shift correction. The averages in Eq. (7) are taken from a large sample of events. In this analysis, the correction is done up to the 20th harmonic. This was done to make the \( \chi^2 \) divided by the number of degrees of freedom of a flat fit to the event plane azimuthal angle distribution to be less than 1. The distributions of \( \Psi_2^\text{east} \) and \( \Psi_2^\text{west} \) are separately flattened and then the full-event event plane distribution is flattened. Accordingly, the observed \( v_2 \) and resolution are calculated using the shifted (sub)event plane azimuthal angles:

\[
\Psi' = \Psi + \sum_{n} \frac{1}{n} \left( -\langle \sin(2n\Psi) \rangle \cos(2n\Psi) + \langle \cos(2n\Psi) \rangle \sin(2n\Psi) \right). \quad (7)
\]

3. Scalar product method

The scalar product method [30, 40] is similar to the event plane method and gives \( v_2 \) as

\[
v_2(p_T) = \frac{\langle Q^2 w_i^* (p_T) \rangle}{2 \sqrt{\langle Q^2 \rangle \langle Q^2^* \rangle}}, \quad (8)
\]
where \( u_{2,i} = \cos(2\phi_i) + i \sin(2\phi_i) \) is a unit vector of the \( i \)th particle and \( Q_2 = \sum_i u_{2,i} \) is the flow vector with the sum running over all other particles \( k \) in the event. The superscript * denotes the complex conjugate of a complex number. \( A \) and \( B \) denote the two events. In the case that \( Q_2 \) is normalized to a unit vector, Eq. (8) reduces to the event plane method. In the scalar product method, one can use a different (recentering) technique [41] to correct for detector effects, which presents an alternative to the weighting and shifting procedures described in Secs. II C1 and II C2 above. The scalar product method is applied to the \( v_2 \) measurement of charged hadrons.

### D. \( v_2 \) versus \( m_{inv} \) method

For \( v_2 \) of the identified particles \( K^0_S, \phi, \Lambda, \) and \( \Xi \), the \( v_2 \) versus \( m_{inv} \) method is used [31,42]. Because \( v_2 \) is additive, one can write the total \( v_2^{Sig+Bg} \) as a sum of signal and background contributions weighted by their relative yields:

\[
v_2^{Sig+Bg}(m_{inv}) = v_2^{Sig}(m_{inv}) + v_2^{Bg}(m_{inv}) \frac{Bg}{Sig+Bg}(m_{inv}). \tag{9}
\]

This method involves the calculation of \( v_2^{Sig+Bg} \) as a function of \( m_{inv} \) and then fitting the distribution using Eq. (9) with measured relative yields and parametrizations of \( v_2^{Sig} \) and \( v_2^{Bg} \). The \( (Bg/Sig+Bg)(m_{inv}) \) distribution is the \( Bg \) divided by \( (Sig+Bg) \). The \( (Sig/Sig+Bg)(m_{inv}) \) distribution is simply calculated by \( 1 - (Bg/Sig+Bg)(m_{inv}) \). The term \( v_2^{Bg} \) is parametrized as a linear function to take care of the nonconstant \( v_2^{Bg} \) value as a function of \( m_{inv} \). The fit result \( v_2^{Sig} \) is the final observed \( v_2 \). Why this method works well for measuring signal \( v_2 \) is explained as follows: a set of data points is used in the fit over a wide \( m_{inv} \) region for \( Sig \) and \( Bg \). Data points far from the mass peak constrain \( v_2^{Bg}(m_{inv}) \), because \( Bg \) is expected in this region. Under the peak, \( v_2^{Sig+Bg}(m_{inv}) \) is dominated by the \( Sig \) distribution. Finally, the \( v_2 \) signal is extracted by the fitting method shown in Eq. (9).

Note that the subtraction procedure used to extract the \( v_2 \) signal for a given identified particle is independent of the flow correlations. The \( v_2 \) distributions of the overall signal and background are evaluated by one of the flow analysis methods discussed in Secs. II C1–II C3. In this article, the event plane method with the FTPC event plane is applied for \( K^0_S, \phi, \Lambda, \) and \( \Xi \).

### E. Nonflow contribution for various methods

The method of determining \( v_2 \) using cumulants of various orders has been shown to eliminate nonflow correlations. However, the method is useful only for large values of flow and multiplicity. For the relatively low values of flow and multiplicity seen in \( Cu + Cu \) collisions, the nonflow correlations have been estimated, as described subsequently.

The event plane method with the TPC event plane is sensitive to nonflow effects. Particles of interest tend to correlate with particles used in the flow vector calculation because of short-range nonflow correlations. Also, particles of two random subevents tend to have those correlations. Thus, nonflow exists in both the observed \( v_2 \) [Eq. (4)] and the resolution [Eq. (6)]. To reduce nonflow effects due to short-range correlations, we take advantage of the large \( \eta \) gap between the two FTPCs sitting at the two sides of the collision in the forward regions. Nonflow is reduced by the \( \eta \) gap between the TPC and FTPCs, but this may not be large enough to remove all nonflow correlations. Thus, we investigate these effects by comparing the azimuthal correlations measured in Cu + Cu to those in \( p + p \) collisions, where all correlations are assumed to be of nonflow origin [43]. Taking into account the nonflow contribution, the numerator of Eq. (8) can be written as follows [30,43]:

\[
(\langle Q_2 u_{2,i}(p_T) \rangle - \langle Q_2 u_{2,i}(p_T) \rangle_{AA}) = M v_2(p_T)\bar{v}_2 + \text{nonflow}, \tag{10}
\]

where \( \phi_{pr} \) is the azimuthal angle of particles from a given \( p_T \) bin \( u_{2,i} \) in Eq. (8) and the sum goes over all tracks \( k \) in an event used to determine the flow vector \( Q_2 \) in Eq. (8). The angled brackets denote averaging over the events. The first term in the right-hand side of Eq. (10) represents the contribution from the flow vector. \( v_2(p_T) \) is the value of elliptic flow at a given \( p_T \). \( \bar{v}_2 \) is the elliptic flow on average for all particles used in the sum of Eq. (10). The multiplicity of particles contributing to the sum is denoted by \( M \). All other correlations subject to nonflow go to the second term in the right-hand side of Eq. (10).

It is assumed that the quantity \( (\langle Q_2 u_{2,i}^2(p_T) \rangle) \) in \( p + p \) collisions can be used to estimate the nonflow in AA collisions [40,43]:

\[
M v_2(p_T)\bar{v}_2 = (\langle Q_2 u_{2,i}^2(p_T) \rangle)_{AA} - (\langle Q_2 u_{2,i}^2(p_T) \rangle)_{pp}. \tag{11}
\]

Dividing both sides by \( 2\sqrt{(\langle Q_2^4 \rangle)_{AA}} \) as in Eq. (8) gives

\[
v_2(\langle AA - pp \rangle(p_T)) = \frac{(\langle Q_2 u_{2,i}^2(p_T) \rangle)_{AA} - (\langle Q_2 u_{2,i}^2(p_T) \rangle)_{pp}}{2\sqrt{(\langle Q_2^4 \rangle)_{AA}}} \tag{12}
\]

because \( 2\sqrt{(\langle Q_2^4 \rangle)_{AA}} = 2\sqrt{(M/2)\bar{v}_2(M/2)\bar{v}_2} = M\bar{v}_2 \).

Comparing \( p + p \) and AA collisions, one might expect some changes in particle correlations: there could be an increase in correlations due to a possible increase of jet multiplicities in AA collisions or, conversely, some decrease due to the suppression of high \( p_T \) back-to-back correlations [44]. However, AA collisions exhibit long \( \eta \) range correlations (the “ridge”) [45,46], which are not seen in \( p + p \) collisions and the origin of which is under investigation [47]. Thus it is difficult to make an accurate estimate of nonflow contributions. The fact that at high \( p_T \) (\( p_T > 5 \text{ GeV/c} \)) the \( p + p \) results are very close to central \( Cu + Cu \) [40,43] suggests that the uncertainties are relatively small. In the following we estimate the systematic uncertainties arising from nonflow contributions. We use \( v_2(\langle AA - pp \rangle, \text{TPC}) \) and \( v_2(\langle AA - pp \rangle, \text{FTPC}) \) to denote \( v_2(\langle AA - pp \rangle) \) calculated with TPC and FTPC flow vectors, respectively.
FIG. 2. (Color online) Charged hadron azimuthal correlations as a function of $p_T$ in $\sqrt{s_{NN}} = 200$ GeV 60% most central Cu + Cu collisions (solid squares) compared to those from $\sqrt{s_{NN}} = 200$ GeV $p + p$ collisions (open squares). Flow vector calculated from (a) TPC tracks and (b) FTPC tracks. The error bars are shown only for the statistical uncertainties.

III. SYSTEMATIC UNCERTAINTIES

Nonflow is one of the largest uncertainties in elliptic flow measurements. As we mentioned in Sec. II C, this effect can be investigated by comparing the azimuthal correlations measured in Cu + Cu collisions to those in $p + p$ collisions. The event average of the sum of the correlations is given by Eq. (10).

Figure 2 shows the azimuthal correlation, Eq. (10), as a function of $p_T$ for the 0%–60% centrality range in Cu + Cu collisions at $\sqrt{s_{NN}} = 200$ GeV, compared to $p + p$ collisions. As we can see, the azimuthal correlations in Cu + Cu collisions, shown as solid squares, increase with $p_T$ and then saturate above 2 GeV/c while those in $p + p$ collisions, shown as open squares, monotonically increase with $p_T$ in the case of the TPC flow vector. With the flow vector determined from FTPC tracks the azimuthal correlations around midrapidity in $p + p$ collisions are small when $p_T$ is less than 4 GeV/c. This means that one strongly reduces the nonflow effects with the FTPC flow vector relative to the one seen with the TPC flow vector.

To illustrate the sensitivity to nonflow for the various flow analysis methods, we first analyzed $h^\pm$ elliptic flow in the 60% most central Cu + Cu collisions at $\sqrt{s_{NN}} = 200$ GeV. As shown in Fig. 3(a), the fact that $v_2$ [TPC] is significantly larger than $v_2$ [FTPC] indicates a larger nonflow effect in $v_2$ [TPC]. With the large $\eta$ gap between west and east FTPCs, nonflow effects due to the short-range correlations are reduced in $v_2$ [FTPC]. $v_2$ [FTPC] saturates at $p_T \sim 2.5$ GeV/c and then falls off slightly up to $p_T \sim 4$ GeV/c. To estimate the remaining nonflow effects in $v_2$ [FTPC], we subtract the azimuthal correlations of $p + p$ collisions from those in Cu + Cu collisions according to Eq. (12). In Fig. 3(a), $v_2$ [AA – pp, FTPC] is close to $v_2$ [FTPC] in the region $p_T < 4$ GeV/c. To quantitatively illustrate nonflow systematic uncertainties, Fig. 3(b) shows the ratios of $v_2$ [AA – pp, FTPC] to $v_2$ [FTPC], $v_2$ [AA – pp, TPC] to $v_2$ [AA – pp, FTPC], and $v_2$ [FTP] to $v_2$ [TPC] as a function of $p_T$. $v_2$ [FTPC]/$v_2$ [TPC] shows that nonflow in $v_2$ [TPC] increases from 20% at $p_T \sim 0.8$ GeV/c to 40% at $p_T \sim 3.5$ GeV/c. Based on the comparison between $v_2$ [AA – pp, FTPC] and $v_2$ [FTPC], the residual nonflow in $v_2$ [FTPC] is less than 10% below $p_T \sim 4$ GeV/c. We also checked the $v_2$ [AA – pp] calculated with the TPC flow vector. Beyond $p_T \sim 3$ GeV/c, $v_2$ [AA – pp, TPC] seems systematically lower, but within errors it is similar to $v_2$ [AA – pp, FTPC]. This shows that most of the nonflow is eliminated by subtracting the azimuthal correlation in $p + p$ collisions, validating our earlier assumption.

To illustrate the centrality dependence of the systematic uncertainties, Fig. 4 shows $v_2$ [FTP] and $v_2$ [AA – pp, FTPC] as a function of $p_T$ for six centrality bins. Ratios of $v_2$ [AA – pp, FTPC] to $v_2$ [FTP] for each centrality bin are shown in Fig. 5 from (a) the most peripheral bin 50%–60% to (f) the most central bin 0%–10%. For each centrality bin, the ratio falls off slightly as $p_T$ increases. For the two peripheral bins 50%–60% and 40%–50%, the ratios drop faster than in the other bins, indicating larger nonflow contributions in $v_2$ [FTP]($p_T$) in peripheral Cu + Cu collisions. Figure 6 shows charged hadron $v_2$ integrated over $p_T$ (0.15 < $p_T$ < 4 GeV/c) and $\eta$ (|$\eta$| < 1.0) vs centrality for the various methods. It is clear that $v_2$ [TPC] is much higher than for the other methods, especially for the peripheral collisions.
and hadrons as a function of \( p_T \) in \( \sqrt{s_{NN}} = 200 \) GeV Cu + Cu collisions for centrality bins: (a) 50%–60%, (b) 40%–50%, (c) 30%–40%, (d) 20%–30%, (e) 10%–20%, and (f) 0%–10%. The percentages refer to fractions of most central events. The error bars are shown only for the statistical uncertainties.

To summarize the nonflow systematics we employed the scalar product method with TPC and FTPC flow vectors for \( h^\pm \) in Cu + Cu collisions at \( \sqrt{s_{NN}} = 200 \) GeV. The results for the 60% most central events are shown in Fig. 3. \( v_2\) (TPC) has large nonflow contributions while \( v_2\) (FTPC) eliminates most of the nonflow. In what follows, we report our results in terms of \( v_2\) (FTPC). For simplicity \( v_2\) denotes \( v_2\) (FTPC) except when the flow method is explicitly specified. With the assumption of pure nonflow effects in \( p + p \) collisions, we use \( v_2\) (AA – pp, FTPC) to estimate nonflow systematic errors in \( v_2\) (FTPC). Ratios of \( v_2\) (AA – pp, FTPC) to \( v_2\) (FTPC) are shown for the 60% most central events in Fig. 3(b) and six centrality bins in Fig. 5. The ratios show that nonflow effects increase with \( p_T \) for all centrality bins and nonflow effects are larger in more peripheral bins. To estimate the nonflow systematic error in \( v_2\) (FTPC), we fitted a constant to the ratio \( v_2\) (AA – pp, FTPC)/\( v_2\) (FTPC) in the \( p_T \) range (0, 4 GeV). We take the numerical value of this constant as the estimate of the systematic uncertainty. The resulting nonflow systematic error is minus 5% for 0%–10%, 10%–20%, 20%–30%, 30%–40% collisions and minus 10% for 40%–50% and 50%–60% collisions. Although for \( v_2\) of \( K^0_S \), \( \phi \), \( \Lambda \), and \( \Xi \) the nonflow effects may be different, because we don’t have enough statistics to repeat the analysis we simply assume a similar magnitude for the nonflow systematic error.

The other systematic uncertainties in the \( v_2\) analysis procedure are studied as follows. We estimate the systematic errors from the shifting method for the FTPC event plane by comparing \( v_2\) using different maximum harmonics in Eq. (7) and find the systematic errors are less than 1%. The systematic errors in \( K^0_S \) and \( \Lambda \) \( v_2\) resulting from the background uncertainty and topological cut criteria are estimated using the event plane method. The uncertainty due to the background subtraction is estimated as the relative differences in \( v_2\) from fitting the background using second- and fourth-order polynomials. The systematic uncertainty is also estimated by varying the cut parameters. The systematic errors for \( K^0_S \) and \( \Lambda \) from the background uncertainty and the cut criteria are summarized in Table I. From Ref. [31], the estimated systematic uncertainty of \( \Lambda \) from feed-down is less than 2%.

### IV. RESULTS AND DISCUSSION

#### A. Charged hadrons

Flow results for charged hadrons were determined using the scalar product method Eq. (8) with the flow vector derived from the FTPC tracks. A comparison to \( v_2\) (AA – pp, FTPC) Eq. (12) was used to estimate the systematic error. Figure 7 shows \( v_2\) of \( h^\pm \) for six centrality bins from Cu + Cu collisions.

**TABLE I. Summary of systematic errors of \( v_2\) due to the reconstruction procedure of strange hadrons in Cu + Cu collisions at \( \sqrt{s_{NN}} = 200 \) GeV.**

| Centrality | \( K^0_S \) Error | \( \Lambda \) Error |
|------------|-------------------|-------------------|
| 0%–60%     | 1%                | 1%                |
| 0%–20%     | 1%                | 1%                |
| 20%–60%    | 4%                | 5%                |

FIG. 4. (Color online) Charged hadron \( v_2\) (FTPC) (solid circles) and \( v_2\) (AA – pp, FTPC) (open circles) as a function of \( p_T \) in \( \sqrt{s_{NN}} = 200 \) GeV Cu + Cu collisions for centrality bins: (a) 50%–60%, (b) 40%–50%, (c) 30%–40%, (d) 20%–30%, (e) 10%–20%, and (f) 0%–10%. The percentages refer to fractions of most central events.

FIG. 5. Ratios of \( v_2\) (AA – pp, FTPC)/\( v_2\) (FTPC) for charged hadrons as a function of \( p_T \) in \( \sqrt{s_{NN}} = 200 \) GeV Cu + Cu collisions for centrality bins: (a) 50%–60%, (b) 40%–50%, (c) 30%–40%, (d) 20%–30%, (e) 10%–20%, and (f) 0%–10%. The percentages refer to fractions of most central events.

FIG. 6. (Color online) Charged hadron \( v_2\) integrated over \( p_T \) and \( \eta \) vs centrality for the various methods described in the text in \( \sqrt{s_{NN}} = 200 \) and 62.4 GeV Cu + Cu collisions. The error bars are shown only for the statistical uncertainties.

TABLE I. Summary of systematic errors of \( v_2\) due to the reconstruction procedure of strange hadrons in Cu + Cu collisions at \( \sqrt{s_{NN}} = 200 \) GeV.
Collisions at $\sqrt{s_{NN}} = 200$ and 62.4 GeV. For a given centrality bin, $v_2(p_T)$ initially increases with $p_T$. At higher $p_T(p_T > 2$ GeV/$c$), $v_2$ appears to saturate or decrease. $v_2(p_T)$ in more peripheral collisions increases faster and reaches higher values as expected for the larger eccentricity.

At low $p_T$, the increase of $v_2(p_T)$ with $p_T$ is consistent with predictions from ideal hydrodynamic calculations, which will be shown in Fig. 9 for identified particles. The model predicts that $v_2$ continues increasing beyond $p_T \sim 2$ GeV/$c$. The observed saturation or decrease of $v_2(p_T)$ indicates that the model is not valid in this region. One expects that the model should be valid up to higher $p_T$ in a system with larger densities and larger volumes. This was observed in 200 GeV Au + Au collisions [48] where $v_2(p_T)$ of $h^\pm$ saturated at higher $p_T$ in more central collisions. However, we do not observe the strong centrality dependence of saturation $p_T$ for 200 GeV Cu + Cu collisions.

Figure 8 shows the comparison of $v_2$ for $h^\pm$ from $\sqrt{s_{NN}} = 62.4$ and 200 GeV Cu + Cu collisions. The $p_T$ dependence of $v_2$ at the two energies is similar.

**B. Identified hadrons**

The event plane method Eqs. (2)–(5) with the event plane determined from the FTPC tracks was applied to $K_0^0$, $\Lambda$, $\Xi$, and $\phi$. The results are shown in Fig. 9 for the 60% most central events and also for the 0%–20% and 20%–60% centrality bins at midrapidity $|y| < 1$. Because of limited statistics, $\Xi$ and $\phi$...
are only shown for the 0%–60% bin. The results from ideal hydrodynamic calculations [49,50] for each centrality bin are shown for \( \pi, K, p, \phi, \Lambda, \Xi, \) and \( \Omega \), which are displayed by the curves from top (bottom) to bottom (top) for the \( p_T (m_T - m) \) dependence.

The gross features of \( p_T \) dependence and hadron-type dependence are similar to those observed in 200 GeV Au + Au collisions [31]. At low \( p_T \), the hadron mass hierarchy [at a given \( p_T \), the heavier the hadron, the smaller the \( v_2(p_T) \)] is reproduced by ideal hydrodynamic calculations. [See Fig. 10(a) for clarity.] Multiple-strange-quark hadrons \( \Xi \) and \( \phi \), which participate less in later hadronic interactions than do single-strange-quark hadrons \( K^0_S \) and \( \Lambda \), have sizable \( v_2 \). In particular, \( \Xi \) is consistent with the mass ordering shown in Fig. 9(a1). While the model can roughly reproduce the magnitude of the data for the 60% most central events sample, there is an obvious disagreement in centrality selected data. The model underpredicts \( v_2(p_T) \) in the 0%–20% bin while it overpredicts the data in the 20%–60% bin. Effects not included in the model that may be relevant are geometrical fluctuations in the initial conditions and finite viscosity effects. It is unclear whether these effects can account for the difference between the model and the data.

At higher \( p_T \), the hydrodynamic model mass ordering breaks. \( v_2(p_T) \) appears to depend on hadron type: \( v_2(p_T) \) is grouped by mesons and baryons, with magnitude depending on the number of quarks within the mesons or baryons. Over the entire \( p_T \) region, both the data and the model exhibit the same qualitative centrality dependence as observed for 200 GeV Au + Au collisions [31]: the more peripheral the collision, the larger the \( v_2 \) values. Compared to the results for 200 GeV Au + Au collisions [31], the splitting of \( K^0_S \) and \( \Lambda \) \( v_2(p_T) \) is smaller in both the mass ordering region and the hadron-type dependence region. This indicates smaller collective flow in Cu + Cu than Au + Au collisions, which will be seen more clearly in Sec. IV D.

The transverse kinetic energy scaling first observed in Au + Au collisions is also tested in Fig. 9. The results in Figs. 9 (a1)–9(a3) are replotted as a function of the transverse kinetic energy \( m_T - m \) in Figs. 9 (b1)–9(b3). The quantity \( m \) denotes the rest mass of a given hadron. In the low \( m_T - m \) region, \( v_2(m_T - m) \) is a linearly increasing function and independent of hadron mass. Transverse kinetic energy scaling holds in the region \( m_T - m < 0.8 \text{ GeV}/c^2 \), as observed in Au + Au collisions [31,51]. Calculations using ideal hydrodynamics are shown in each panel as a function of \( m_T - m \). Contrary to the mass ordering as a function of \( p_T \), the model shows the reversed mass ordering as a function of \( m_T - m \): the heavier the hadron, the larger the \( v_2(m_T - m) \) value. The results of \( K^0_S, \Lambda, \) and \( \Xi \) exhibit \( m_T - m \) scaling in each centrality bin, while the model does not show any scaling. Because no pion results are available, the scaling test of the data is not conclusive. All these effects can be seen more clearly in Fig. 10.

C. Quark-number scaling

In Au + Au collisions in the intermediate \( p_T \) region, \( 2 < p_T < 4 \text{ GeV}/c \), the baryon-meson grouping of \( v_2(p_T) \) follows the number-of-quark scaling: the \( v_2 \) of all hadrons fall onto an universal curve once \( v_2 \) and \( p_T \) are divided by the number of quarks, \( n_q \), in a given hadron [31,52]. The observed scaling can be explained by the coalescence or recombination models [22,53,54], indicating the constituent quark degree of freedom has been manifested before hadronization takes place.

\[
\frac{f_{v_2}(p_T)}{n_q} = \frac{a}{1 + e^{-(p_T/n_q - b)/c}} - d, \tag{13}
\]

has been fitted to the data both in \( p_T \) and \( m_T - m \) for each centrality bin. In this formula, \( a, b, c, \) and \( d \) are fit parameters and \( n_q \) is the number of quarks. The \( n_q \) scaling is observed for \( p_T/n_q > 0.8 \text{ GeV}/c \), whereas it is seen for the entire \( (m_T - m)/n_q \) region. Below \( (m_T - m)/n_q \sim 0.4 \text{ GeV}/c^2 \), the \( m_T - m \) scaling that was established at low \( p_T \), now scaled by \( n_q \), leads to the combined \( (m_T - m)/n_q \) scaling. The universal \( n_q \) scaling of \( v_2 \) suggests the manifestation of early partonic dynamics in both Au + Au and Cu + Cu collisions..
D. Centrality and system-size dependence

The centrality and system-size dependence of \( v_2 \) is related to the physics of the system created in high-energy nuclear collisions. In the ideal hydrodynamic limit the centrality dependence of elliptic flow is mostly defined by the elliptic anisotropy of the overlapping region of the colliding nuclei, and in the low-density limit it is mostly defined by the product of the elliptic anisotropy and the multiplicity. Thus, the centrality and system-size dependence of elliptic flow should be a good indicator of the degree of equilibration reached in the reaction [28].

For a study of the centrality dependence of \( v_2(p_T) \) in Cu + Cu collisions together with Au + Au collisions, we divide \( v_2(p_T) \) by the initial spatial anisotropy, eccentricity, to remove this geometric effect. The participant eccentricity is the initial configuration space eccentricity of the participants, which is defined by [56]

\[
\epsilon_{\text{part}} = \sqrt{\frac{\sigma_x^2 - \sigma_y^2}{\sigma_x^2 + \sigma_y^2}} + 4\frac{\sigma_{xy}}{\sigma_x^2 + \sigma_y^2}.
\]

In this formula, \( \sigma_x^2 = (x^2) - (x)^2 \), \( \sigma_y^2 = (y^2) - (y)^2 \), and \( \sigma_{xy} = (xy) - (x)(y) \), with \( x, y \) being the position of the participating nucleons in the transverse plane. The root mean square of the participant eccentricity,

\[
\epsilon_{\text{part}}(2) = \sqrt{\langle \epsilon_{\text{part}}^2 \rangle},
\]

is calculated from the Monte Carlo–Glauber model [29,57] and the color glass condensate (CGC) model [58–61]. (See Table II for \( \epsilon_{\text{part}}(2) \).) Because the FTPC event plane is constructed from the hadrons that have their origin in participant nucleons and the FTPC event plane resolution is less than 0.2, what we actually measure is the root mean square of \( v_2 \) with respect to the participant plane [62]. In this case, \( \epsilon_{\text{part}}(2) \) is the appropriate measure of the initial geometric anisotropy taking the event-by-event fluctuations into account [62–64]. Figure 12 shows the centrality dependence of \( v_2(p_T)/\epsilon_{\text{part}}(2) \) for \( h^+ \) in 200 and 62.4 GeV Cu + Cu collisions. For a given centrality bin, \( v_2(p_T)/\epsilon_{\text{part}}(2) \) initially increases with \( p_T \) and then flattens or falls off at higher \( p_T \). After the geometric effect is removed, the ordering of the distributions as a function of centrality, observed in Fig. 7, is reversed: the more central the collision, the higher the \( v_2(p_T)/\epsilon_{\text{part}}(2) \). This suggests that the strength of collective motion is larger in more central collisions.

To further study the centrality dependence of strange hadron \( v_2 \), we normalized the \( n_q \) scaled values by \( \epsilon_{\text{part}}(2) \) and plotted them as a function of \( (m_T - m)/n_q \). The centrality dependence of \( K^0_S \) and \( \Lambda \) results are shown in Fig. 13. The solid symbols

| Centrality | \( \epsilon_{\text{part}}(2) \) (CGC) | \( \epsilon_{\text{part}}(2) \) (Glauber) | \( N_{\text{part}} \) |
|------------|-----------------------------------|-----------------------------------|----------------|

| 40%–50%    | 0.490 ± 0.002                     | 0.550 ± 0.021                     | 26 ± 1         |
| 50%–60%    | 0.555 ± 0.004                     | 0.643 ± 0.031                     | 17 ± 1         |
Theoretical analyses found that the centrality and system-size dependence of $v_2$ can be described by a simple model based on eccentricity scaling and incomplete thermalization. Within these models the lack of perfect equilibration allows slightly different ($\sim 10\%$ larger) from the previous published results [31], which were calculated directly from the wide centrality bins. From top to bottom, the results are from $0\%$–$10\%$, $10\%$–$40\%$, and $40\%$–$80\%$ centrality bins. For clarity, $K_0^0$ and $\Lambda$ results are shown in different panels. Curves represent $n_q$ scaling fits from Eq. (13) normalized by $\varepsilon_{\text{part}}(2)$ to the combined data of $K_0^0$ and $\Lambda$ for five centrality bins. For a given centrality, $K_0^0$ and $\Lambda$ results follow a universal curve, which means partonic collective flow is explicitly seen in the measured scaling with $n_q$ and $\varepsilon_{\text{part}}(2)$. For a given collision system, the stronger partonic collective flow is apparent as higher scaled $v_2$ values in more central collisions. To study the system-size dependence of the scaling properties, the results from $0\%$ to $60\%$ centrality $Cu+Cu$ and $0\%$ to $80\%$ Au+Au collisions are shown in Fig. 14. The stronger collective motion in Au+Au collisions compared to that in Cu+Cu collisions becomes obvious, although the constituent quark degrees of freedom have been taken into account in both systems.

In the ideal hydrodynamic limit where dynamic thermalization is reached, the mean free path is much less than the geometric size of the system. The geometric size of the system and the centrality dependence of flow is totally governed by the initial geometry (eccentricity) [28]. Because there is no universal scaling with the eccentricity among either different collision centralities or different collision system sizes, this indicates that the ideal hydrodynamic limit is not reached in $Cu+Cu$ collisions, presumably because the assumption of thermalization is not attained. In addition, $v_2/(n_q\varepsilon_{\text{part}}(2))$ shows an increasing trend as a function of $N_{\text{part}}$ (see Fig. 13). Table II lists the values of eccentricity and $N_{\text{part}}$ for the used centrality bins in Au+Au and Cu+Cu collisions. This suggests that the measured $v_2$ is not only dependent on the initial geometry but also on $N_{\text{part}}$.

Theoretical analyses found that the centrality and system-size dependence of $v_2$ can be described by a simple model based on eccentricity scaling and incomplete thermalization. Within these models the lack of perfect equilibration allows for estimates of the effective parton cross section in the quark-gluon plasma and of the shear viscosity to entropy density ratio.

---

**FIG. 14.** (Color online) Number of quarks and participant eccentricity scaled $v_2 [v_2/(n_q\varepsilon_{\text{part}}(2))]$ of identified particles as a function of $(m_T - m)/n_q$ in $0\%$–$80\%$ Au+Au collisions (open symbols) [31] and $0\%$–$60\%$ Cu+Cu collisions (solid symbols) at $\sqrt{s_{NN}} = 200$ GeV. Circles, squares, and triangles represent the data for $K_0^0$, $\Lambda$, and $\Xi$, respectively. The error bars are shown only for the statistical uncertainties.
(n/s) [33,65]. Thus, the $v_2$ results from Cu + Cu collisions reported in this article should allow extraction of $\eta/s$ and extrapolation to the ideal hydrodynamic limit.

V. SUMMARY

We present STAR results on midrapidity elliptic flow $v_2$ for charged hadrons $h^{\pm}$ and strangeness-containing hadrons $K_{S}^{0}$, $\Lambda$, $\Xi$, and $\phi$ from Cu + Cu collisions at $\sqrt{s_{NN}} = 62.4$ and 200 GeV at RHIC. The centrality dependence of $v_2$ for different system sizes as a function of the transverse momentum $p_T$ is presented. To estimate the systematic uncertainties, we studied various measurement methods. Below $p_T \sim 4 \text{ GeV}/c$, nonflow correlations are reduced with the event plane constructed from hadrons produced in the forward regions $(2.5 < |\eta| < 4.0)$. We obtained an estimate of the systematic uncertainties due to the remaining nonflow contributions based on correlations measured in $p + p$ collisions.

For a given centrality bin, $p_T$ and hadron-type dependencies of strange hadron $v_2$ are similar to those found in Au + Au collisions [31]: (i) In the low $p_T$ region, $p_T < 2 \text{ GeV}/c$, the hadron mass hierarchy is observed as expected in ideal hydrodynamic calculations: at fixed $p_T$, the larger the hadron mass, the smaller the $v_2$. (ii) In the intermediate $p_T$ region, $2 < p_T < 4 \text{ GeV}/c$, $v_2$ as a function of either $p_T$ or $m_T - m$ follows a scaling with the number of constituent quarks $n_q$. Larger $v_2/(n_q \epsilon_{\text{part}}[2])$ values are seen in more central collisions, indicating stronger collective flow developed in more central collisions. The comparison with Au + Au collisions that go further in density shows eccentricity scaled $v_2$ values depend on the system size ($N_{\text{part}}$). This suggests that the ideal hydrodynamic limit is not reached in Cu + Cu collisions, presumably because the assumption of thermalization is not attained.

ACKNOWLEDGMENTS

We thank the RHIC Operations Group and RCF at BNL, the NERSC Center at LBNL, and the Open Science Grid consortium for providing resources and support. This work was supported in part by the Offices of NP and HEP within the US DOE Office of Science; the US NSF; the Sloan Foundation; the DFG cluster of excellence “Origin and Structure of the Universe” of Germany; CNRS/IN2P3, STFC and EPSRC of the United Kingdom; FAPESP CNPq of Brazil; the Ministry of Education and Science of the Russian Federation; NNSFC, CAS, MoST, and MoE of China; GA and MSMT of the Czech Republic; FOM and NWO of the Netherlands; DAE, DST, and CSIR of India; the Polish Ministry of Science and Higher Education; the Korea Research Foundation; the Ministry of Science, Education and Sports of the Republic of Croatia; the Russian Ministry of Science and Technology; and RosAtom of Russia.
