\section*{A B S T R A C T}

A reliable and effective method for simultaneous analysis of trace amount of bromophenols (BPs) in various aqueous samples was developed in this study. The aqueous samples must be acidified after sampling to prevent the fast degradation of bromophenols. Solid-phase extraction was chosen to extract and purify the water samples. High performance liquid chromatography coupled with tandem mass spectrometry with an electrospray ionization source (HPLC-ESI-MS/MS) was used for following identification and quantification. Under the optimized condition, fourteen out of fifteen target brominated phenols were successfully separated and detected with the exception of 2,6-bromophenol (2,6-BP) whose response was too low to be quantified by the MS detector. The method was validated by spiking river water and seawater samples with different concentrations of BPs, and the qualified spiking recoveries (64–100%) and precisions (0.4–11% RSD) were obtained. The method detection limits were 0.1–13.9 ng/L and 0.1–21.9 ng/L for 0.1 L of river water and seawater samples, respectively, showing the influences from the sample matrix. The proposed method was successfully applied to the analysis of bromophenol contamination in real water samples, and six bromophenols were identified with a wide concentrations ranging from ng/L to μg/L.

\section*{1. Introduction}

Brominated phenols (BPs) have high K\textsubscript{ow}, high lipophilicity, and even relatively high water solubility. Among them, 2,4,6-tribromophenol (2,4,6-TBP), 2,4-dibromophenol (2,4-DBP), and pentabromophenol (PBP) are increasingly used as a group of novel brominated flame retardants (BFRs) in epoxy and phenolic resins, as replacements for the banned traditional formulations, such as Penta- and Octa-BDEs which contain BP-like moieties structure. Therefore, BPs may also be degradation products of tetrabromobisphenol A (TBBPA), PBDEs, and other primary BFRs through the photo-transformation under UV irradiation \cite{4}, the thermal degradation \cite{5,6}, and the biological metabolism process \cite{7,8}. 4-BP, 2,4-BP, 2,6-BP and 2,4,6-BP, as the natural products of marine organisms such as algae and polychaetes \cite{9,10}, were also found in sea water \cite{11}, invertebrates \cite{12}, fish and marine mammals \cite{13,14}. Some BPs have been found to exhibit adverse health effects, like endocrine disruption and neurotoxicity to organisms \cite{15–18}.

Originating from anthropogenic and/or natural sources, 2,4,6-TBP, 2,4-DBP were determined in water and aerosol samples \cite{19,20}, soils \cite{21}, as well as sewage sludge \cite{22}, even in human blood and milk \cite{23,24}. Some reports indicated that 2,4,5-TBP, 2,4-DBP and 2,4,6-TBP found in the blood of mice and human \cite{8,25} and in polar bear tissues \cite{14} may be formed via metabolic conversion of OH-PBDEs and PBDEs. Recently, Lin et al. \cite{26} have found that OH-PBDEs could form naturally from simple BPs including 2,4-DBP and 2,4,6-TBP with the catalysis of bromoperoxidase. These complex transformation pathways are of particular concern, and could alter the environmental burdens of BPs and other relevant contaminants. Therefore, well understanding on various BPs in the environment can help not only study the environmental and health risk of BPs themselves, but also learn the...
intermediate level of 1.8 μg/L for BPs is not satisfactory enough, especially for the analysis of pollutants at environmental low levels. Thus, a robust analytical method is still urgently needed.

The aim of this work is to develop an effective and reliable analytical method to achieve simultaneous identification and quantification of various brominated phenols in water samples using LC-MS/MS. The mass spectrometer equipped with an electrospray ionization source was operated in negative-ion mode and performed in multiple reaction monitoring (MRM) mode. Pretreatment procedure was established by optimizing SPE method. Different types of real water samples were analyzed to test the reliability of the method. The developed method was evaluated in terms of linearity, sensitivity, spiking recovery and precision.

2. Experimental section

2.1. Chemicals and materials

Fifteen brominated phenols in toluene, including 3-BP (100 mg/L), 4-BP (100 mg/L), 2,3-BP (100 mg/L), 2,4-BP (100 mg/L), 2,5-BP (100 mg/L), 2,6-BP (100 mg/L), 3,5-BP (100 mg/L), 2,3,4-BP (100 mg/L), 2,4,5-BP (100 mg/L), 2,4,6-BP (100 mg/L), 3,4,5-BP (100 mg/L), 2,3,4,5,6-BP (100 mg/L), and PBP (100 mg/L), were purchased from Waters (Milford, MA, USA). HPLC grade methanol and acetoni-

2.2. Sample collection and preparation

River water sample was collected from Qinghe River, Haidian district, Beijing in April 2014. The sampling site was near a domestic sewage outlet. Swimming pool water sample was collected from an indoor swimming pool in Haidian district, Beijing in May 2014. Coastal sea water samples from Bohai Sea were obtained from Binhai district, Tianjin and Shahekou district, Dalian from April to June, 2014. Waste water sample was collected from a chemical plant in Weifang, Shandong province in June, 2014. Water samples were collected in 4 L amber glass bottles which were pre-cleaned with acetone. After acidified to pH 2.5 with hydrochloric acid on site, samples were transferred back to laboratory instantly and then stored at 4 °C in dark. All the samples were analyzed as soon as possible. Prior to analysis, the water samples were restored to room temperature, and then filtered through Whatman GF/F glass microfiber filters (0.7 μm, Whatman, Maidstone, UK).

2.3. Extraction and clean-up

Solid phase extraction was carried out to extract BPs from aqueous samples. The ultrapure water sample (100 mL), spiked with a mixture of working solutions containing all the target brominated phenols (15 ng for each) and 15 ng 13C-3,5-BP as recovery surrogate standard, was employed to optimize the performance of the method (three replicates). Under the optimized condition, 100–300 mL of real water samples were drawn through the Oasis HLB cartridges at a flow rate of 5 mL/min. The cartridges were firstly conditioned with 7 mL of methanol and 7 mL of water successively. After sample loading, 50 mL of ultrapure water and 5 mL of ultrapure water-methanol solution (4:6, v:v) were used to wash the cartridges in sequence to eliminate the hydrochloric acid and the impurities in samples. After the cartridges were vacuum dried for 20 min, the elution was performed with 6 mL of methanol. The eluents were evaporated to dryness under a gentle stream of nitrogen at 50 °C, and then re-dissolved in ultrapure water-acetonitrile solution (7:3, v:v). Fifteen nanograms of 13C-2,3,4,6- BP was added into the sample vial as injection internal standard, and the final volume of the sample was adjusted to 1 mL.

2.4. LC-MS/MS analysis

The analysis of target BPs was performed using an UltiMate 3000 BioRS ultra high performance liquid chromatograph (Thermo Fisher Scientific Inc., Waltham, MA, USA) coupled with Triple Quad 5500 MS/MS system (AB SCIEX Inc., Framingham, MA, USA). An Accucore C18 column (100 mm×2.1 mm i.d., 2.6 μm particle size, Thermo Fisher Scientific Inc., Waltham, MA, USA) was chosen to separate BPs with the column temperature maintaining at 40 °C. The gradient mobile phase started from 30% methanol (v:v) to 45% in the first 5 min, then increased to 70% within 15 min, and finally to 80% in 5 min. After the program, the composition of the mobile phase return to initial state and held for 8 min to re-equilibrate. The total running for one injection lasted for 33 min with a constant flow rate of 0.4 mL/min. The injection volume was 5 μL.

The mass spectrometer equipped with an electrospray ionization source was operated in negative-ion mode. Details on the Turbo V™ ion sources settings were: temperature 500 °C, curtain gas 40 psi, spray voltage –4500 v, nebulizer gas 50 psi, auxiliary heating gas 50 psi. [M- H]™ was parent ion for each BP analyte, and m/z 79 and 81 were the daughter ions. The determination of 15 targeted BPs was conducted in multiple reaction monitoring (MRM) mode. The parameters optimized to achieve maximum selectivity are shown in Table 1.

2.5. Quality assurance/quality control

The BPs were identified according to the performance criteria for analytical methods by the commission of the European Communities [32]. In short, the relative retention time of the analytes should match that of standards at a tolerance of 2% for liquid chromatography. The calibration curves were constructed using standards with concentrations of 0.1, 0.2, 0.5, 1, 2, 5, 10, 20 and 50 μg/L for each analyte. The
calibration was daily determined to cope with the retention time variations caused by carryover effect. Good linearity with \( r^2 \) over 0.998 was achieved for all the analytes in range of 0.1–50 \( \mu \)g/L. Procedure blanks were added in parallel with every batch of five samples.

On the basis of signal-to-noise ratio of 3 (S/N=3), the equipment detection limits (EDLs) and method detection limits (MDLs) for all the BPs were 0.03–2.4 pg and 0.1–21.9 ng/L, respectively. The spiking recovery and precision were investigated by spiking standard solutions into sea water samples at concentrations of 100 and 1000 ng/L, and river samples at concentration of 150 ng/L. The recoveries of target analytes ranged from 64% to 100%. The relative standard deviations (RSD, \( n=3 \)) were less than 11% for all BPs.

### 3. Results and discussion

Solid phase extraction combined with LC-MS-MS in ESI mode was tested and evaluated regarding the feasibility, rapidness and high throughput of the method. Various parameters affecting the extraction and instrumental detection were optimized in detail as follow.

#### 3.1. Chromatographic separation of BPs

The chromatographic separation solves the co-elution of isomeric compounds. Here four LC columns were tested to achieve the best separation, including Syncronis C18 column (100 mm×2.1 mm, 1.7 \( \mu \)m), Accucore C18 column (100 mm×2.1 mm, 2.6 \( \mu \)m), Accucore PFP column (100 mm×2.1 mm, 2.6 \( \mu \)m), and Acclaim RSLC 120 C18 column (100 mm×2.1 mm, 2.2 \( \mu \)m), which were all purchased from Thermo Fisher Scientific. Among them, Accucore C18 column (100 mm×2.1 mm, 2.6 \( \mu \)m) gave the best selectivity for majority of the BPs.

Different mobile phases and gradient slopes were tested in order to improve the separation resolution and signal intensity. Compared to the performance from the mobile phase of acetonitrile-water system, the mixture of methanol and water enhanced the signal intensity for most target compounds. Fig. 1 shows the total ion chromatogram (TIC) of 14 bromophenols and the internal standard under the optimized condition, with the exception of 2,6-DBP whose response was too low to be quantified by MS detector. The ionization of 2,6-DBP in the MS detector was very hard due to its molecule structure with two Br atoms on both sides of OH substitution. The intensity of 2,6-DBP signal was over two order magnitude lower than that of other BPs and still indiscernible even at a very high injection concentration of 1 mg/L which was much higher than the environment levels.

#### 3.2. Pretreatment procedure

##### 3.2.1. SPE sorbents

According to the different hydrophobicities and polarities of BPs [33], SPE cartridges packed by three sorbents (C18, C8, and Oasis HLB) with distinct characteristics were tested to evaluate the extraction efficiency for BPs. Fig. 2 shows the spiking recoveries (DI water) of BPs. Fig. 2 shows the spiking recoveries (DI water) of BPs based on these different SPE cartridges. C8 cartridges provided poor recoveries for 3-BP and 4-BP ( < 51%). The extraction efficiency of C8 cartridges for the other BPs increased with the increase of bromine atom number on benzene ring, and the good recovery (89%) of pentabromophenol was obtained. For C18 cartridges, the recoveries

| Compounds | Formula | Parent ions (m/z) | Daughter ions (m/z) | Declustering potential (v) | Collision energy (v) |

a The response of 2,6-BP was too low to be detected.
b Internal standards.
were improved to 64% and 58% for monobromophenols, and good recoveries were achieved for the other BPs (88–104%). HLB copolymer cartridges displayed best performance with the highest recoveries (91–110%) and the lowest relative standard deviations (0.7–7%) for all BPs. The differences in extraction efficiencies on three kinds of SPE columns were directly related to the properties of SPE sorbents and the polarities of BPs. 3-BP and 4-BP are more hydrophilic, and have lower affinities with non-polar silica gel sorbents in comparison with tri-, tetra and pentabromophenols [34]. The HLB is a porous polymeric sorbent with an appropriate ratio of the monomers hydrophilic N-vinylpyrrolidone and lipophilic divinylbenzene, providing better reversed-phase capacity for the retention of polar mono-bromophenol molecules [35]. Similar good extraction efficiencies were obtained by HLB cartridges for chlorophenols, the structural analogues of bromophenols [36–38]. Therefore, HLB cartridge was chosen for the subsequent analysis.

3.2.2. Elution solvents

The polarity of elution solvent could affect the recoveries of targeted compounds to a great extent. Methanol [37,39], acetone and ethyl acetate [40,41], which were commonly used for quantitative desorption of phenolic compounds from HLB cartridge, were tested for the elution of BPs. According to Snyder polarity index, the polarities of three elution solvents in an ascending order is ethyl acetate (P′=4.3) < acetone (P′=5.4) < methanol (P′=6.6) [42–44].

As shown in Fig. 3, ethyl acetate presents weakest eluting power towards BPs. Very poor spiking recoveries (<17%) were obtained for tri-, tetra and pentabromophenols compared with mono- and dibromophenols (64–88%). Acetone yielded a little bit better recoveries (40–86%) than ethyl acetate for the analytes, owing to its higher polarity. For ethyl acetate and acetone, the recoveries seemed to systematically decrease with the increase of bromine atoms on bromophenols, because the polarities of these two eluents are not high enough to elute all the analytes. MeOH yielded the best recoveries among three alternative eluents (92–115%) because this high polar protic solvent can elute the polar BPs more efficiently than less polar aprotic solvents (acetone and ethyl acetate). Consequently, methanol was chosen to elute all the BPs from HLB cartridges.

3.3. Acidity of the samples

During the quantitative extraction of phenolic compounds using SPE technique, the pH of the sample is usually considered as a key parameter and the effect has been fully studied [45–48]. Generally, the retention of phenolic compounds from water samples to reverse-phase SPE sorbents is owing to the nonpolar Van der Waals force between analytes and sorbents. Acidiﬁcation of sample solution would keep the phenol compounds in molecular form and increase their affinity towards the sorbents [34]. Here, the effect of pH was also studied by adjusting the samples with hydrochloric acid. The results show that recoveries of analytes remain high and relatively similar at pH range from 2.5 to 6.3 (pure Milli-Q water), indicating not only reversed-phase mechanism but also π-π interaction among electrons from aromatic ring in the sorbent and phenol molecules play roles in extraction process. In addition, the acidity of the samples affected the stabilities of BPs. In our preliminary studies, we found that BPs detected in the river water sample on the day of collection disappeared after 24-h storage in
the lab even at 4 °C. Namely, inappropriate transportation and storage of the water samples led to the inaccurate determination of BPs. To ensure the stability of bromophenols, acidification would be necessary according to the sampling methods of other phenolic compounds. Considering that the pKa value of targeted BPs should be higher than the pH value of water samples, the acidification of water samples to pH 2.5 with hydrochloric acid would be necessary.

To examine the effects of acidity on the stability of various BPs, “blank river water” sample, in which the targeted compounds were not found, was acidified to pH 2.5, spiked with BP standards, and stored at 4 °C without light. Then, the BPs were determined at different storage time points. In the pretreatment process, the SPE column loaded with water samples was firstly washed with 50 mL of ultrapure water to flush the hydrochloric acid off. The results showed that no significant diminution of the recoveries of BPs was found during two-week storage, meaning that the acidification of the samples effectively stabilized the targeted BPs. Fig. 4 shows the recovery-time curve of five BPs which was selected randomly to represent the same substituted bromophenols regarding bromine atom number. Therefore, the acidification of the samples to pH 2.5 on site was performed for water sample collection avoiding the unnecessary degradation of the target compounds.

3.4. Performance of the method

The developed method was validated and evaluated in terms of linearity, sensitivity, spiking recovery and precision under the optimized condition, and the results were summarized in Table 2. Apparently, good linearity was obtained with the linear regression coefficient (r²) higher than 0.998 when the concentrations of BPs ranged from 0.1 to 50 μg/L. The behaviors of different BPs on LC-MS/MS were significantly different. The equipment detection limits (EDLs) varied from 0.03 to 0.2 pg for most of bromophenols. However, the detection sensitivities of 2,4,6-BP, 2,5-BP, and 2,4-BP are relatively low with the EDLs of 0.7, 2.1, and 2.4 pg, respectively. The sample matrix affected the determination to some extent. When compared to seawater samples, BPs in river water had lower method detection limits (MDLs) and better spiking recoveries. The MDLs of 2,4,6-BP and 2,4-BP in this study were close to the previously reported results based on GC/MS analysis [11,19]. While the MDL of pentabromophenol in this study was 10 folds lower than that of GC/MS method [11,27,28]. As for the other BPs which were not focused on in previous studies, high signal responses and low MDLs were obtained in this work. The high sensitivity of this method is helpful for the detection of trace amounts of BPs in aquatic system, which may provide the useful information on their environmental occurrence, distribution and fate. The average recoveries of all compounds ranged from 64% to 100%. The precision of the method, expressed as the relative standard deviations (RSD, n=9), were all less than 11%. All parameters, including linearity, sensitivity, recovery and precision of the method, demonstrated that it was reliable and suitable for simultaneous analysis of various brominated phenols.

3.5. Analysis of real samples

The proposed method was applied to study the occurrence of BPs in various aqueous samples, including river water, swimming pool water, factory discharge wastewater and seawater (Table 3).

The wastewater sample discharged from a factory producing flame retardants contained relatively high concentrations of bromophenols, in which 2,4,6-TBP was dominant compound and its level was up to 7062.5 ng/L. The concentration of 2,4,6-TBP exceeded its olfactory taste threshold (600 ng/L) with the characteristic earthy-musty odor [49,50]. Besides common BPs, such as 4-BP, 2,4-DBP and 2,4,6-TBP present in various environmental samples, 3-BP, 2,3-DBP and 3,5-DBP were also detected at a wide range of concentrations (2.6–1813.8 ng/L). All the bromophenols in wastewater sample might be attributed to the industrial production, as the by-products of TBBPA and other brominated flame retardants which are the major products of the factory.

4-BP is generally considered as the natural product of marine algae instead of industrial material. However, 4-BP was detected in all the tested water samples. Its concentration was 44.9 ng/L in the river sample, which was relatively high because the sampling location was near a domestic sewage outlet. Considering the production of natural BPs rarely occur in fresh water, 4-BP detected in Qinghe River might originate from the anthropogenic input and the degradation of other widely used BFRs. As one of typical halogenated disinfection byproducts in chlorinated pool water, 4-BP was also confirmed at a very low concentration of 1.6 ng/L in a swimming pool, resulting from the interaction between residual chlorine in water and human body substances (such as urine) in the presence of bromide [51].

For seawater samples, 4-BP, 2,4-BP and 2,4,6-BP were detected from two coastal sites at different levels. In coastal seawater from Dalian, 2,4-BP and 2,4,6-BP were dominant with the concentrations of 27.5 and 26.2 ng/L, respectively, which were comparable to the results achieved in German Bight (2–48 ng/L for 2,4-BP and n.d.–6 ng/L for 2,4,6-BP) and southeastern coastal areas of Korea (n.d.–32.7 ng/L for 2,4-BP and 0.38–20.2 ng/L for 2,4,6-BP) [11,52]. 2,4-BP and 2,6-BP were found in seawater from Tianjin with higher levels of 103.7 and 68.4 ng/L, related to the different sampling locations and sources. 4-BP was detected from both sites at low levels in contrast to the findings in previous reports [11,52]. Besides the natural formation by marine biota, various anthropogenic sources affected the coastal areas. It is difficult to determine whether the compounds are biogenic or anthropogenic origin [19,52].

4. Conclusions

A reliable and efficient analytical approach was developed and validated for the determination of bromophenols by SPE and LC-MS/MS. It allows, for the first time, simultaneous analysis of 14 BPs with different substitutions in the environmental aqueous samples. The good linearity, sensitivity, recovery, and precision were validated for the newly-developed method, showing it was very promising in environmental analysis. The optimized method was finally applied to the determination of BPs in several kinds of water samples. Two mono-bromophenols, three di-bromophenols and 2,4,6-tribromophenol were found in the water samples. It was also found that BPs were not stable in the natural water system. The proposed method is practical and effective to investigate the occurrence and distribution of trace levels of BPs in diverse water matrices. It was also helpful in exploration on the
Table 2
The performance of the method. The linearity ranges for all BPs were from 0.1 to 50 µg/L.

| Compound | Limit of detection (µg/L) | Linear regression coefficient (r²) | Spiking recovery (%) | RSD (%) |
