Abstract

We extend our previous studies of double-parton scattering (DPS) to simultaneous production of $c\bar{c}$ and $b\bar{b}$ and production of two pairs of $b\bar{b}$. The calculation is performed within factorized ansatz. Each parton scattering is calculated within $k_T$-factorization approach. The hadronization is done with the help of fragmentation functions. Production of $D$ mesons in our framework was tested in our previous works. Here we present our predictions for $B$ mesons. A good agreement is achieved with the LHCb data. We present our results for $c\bar{c}b\bar{b}$ and $b\bar{b}b\bar{b}$ final states. For completeness we compare results for double- and single-parton scattering (SPS). As for $c\bar{c}c\bar{c}$ final state also here the DPS dominates over the SPS, especially for small transverse momenta. We present several distributions and integrated cross sections with realistic cuts for simultaneous production of $D^0B^+$ and $B^+B^+$, suggesting future experimental studies at the LHC.

I. INTRODUCTION

Phenomena of multiple-parton interaction (MPI) have become very important for precise description of high-energy proton-proton collisions in the ongoing LHC era. There are several experimental and theoretical studies of soft and hard MPI effects in progress (see e.g. Refs. [1, 2]), so far mostly concentrated on double-parton scattering (DPS). In many cases exploration of DPS mechanisms for different processes needs dedicated experimental analysis and is strongly limited because of large background coming from standard single-parton scattering (SPS).

Some time ago we proposed and discussed double open charm meson production $pp \rightarrow DDX$ as a potentially one of the best reaction to study hard double-parton scattering effects at the LHC [3]. This conclusion was further confirmed by the LHCb collaboration that has reported surprisingly large cross sections for $DD$ meson-meson pair production in $pp$-scattering at 7 TeV [4]. As we have shown in our subsequent studies the LHCb double charm data cannot be explained without the DPS mechanism [5]. In this case the standard SPS contribution is much smaller and the data sample is clearly dominated by the DPS component [6, 7].

Subsequently, we have done similar phenomenological studies for other final states. We identified optimal conditions for exploring DPS effects in $pp \rightarrow 4 \text{jets} X$ [8, 9] as well as in $pp \rightarrow D^0 + 2 \text{jets} X$ and $pp \rightarrow D^0D^0 + 2 \text{jets} X$ [10] reactions for the ATLAS experiment. Very recently, we have also discussed for the first time possible observation of triple-parton scattering (TPS) mechanism in triple open charm meson production with the LHCb detector [11]. Some rather general features of double-parton scattering were discussed previously both for $bb\bar{b}\bar{b}$ [12] and $cc\bar{b}\bar{b}$ [13] final states. Here we extend the discussion by including also single-parton scattering mechanism for a first time.

In this paper, we wish to present results of phenomenological studies of DPS effects in the case of associated open charm and bottom $pp \rightarrow D^0B^+ X$ as well as double open bottom $pp \rightarrow B^+B^+ X$ production. In particular, we will show theoretical predictions of integrated and differential cross sections for different energies that could help to conclude whether and how the DPS effects for these two cases can be observed experimentally by the LHCb/CMS collaborations.
II. A SKETCH OF THE THEORETICAL FORMALISM

A. Single-parton scattering

In Fig. 1 we show a diagrammatic representation of the dominant SPS mechanism for double heavy quark pair production. In particular, in the following we consider mixed $c\bar{c}b\bar{b}$ (left panel) and double bottom $bb\bar{b}\bar{b}$ (right panel) final states, however, here the production mechanism is the same as was discussed by us in the case of double charm production (see e.g. Ref. [7]).

In the $k_T$-factorization approach [14–17] the SPS cross section for $pp \rightarrow Q\bar{Q}Q\bar{Q} X$ reaction can be written as

$$d\sigma_{pp \rightarrow Q\bar{Q}Q\bar{Q} X} = \int dx_1 \frac{d^2k_1}{\pi} dx_2 \frac{d^2k_2}{\pi} F_g(x_1, k_{1T}^2, \mu^2) F_g(x_2, k_{2T}^2, \mu^2) d\hat{\sigma}_{gg \rightarrow Q\bar{Q}Q\bar{Q}}. \quad (2.1)$$

In the formula above $F_g(x, k_T^2, \mu^2)$ is the unintegrated gluon distribution function (uGDF). The uGDF depends on longitudinal momentum fraction $x$, transverse momentum squared $k_T^2$ of the gluons entering the hard process, and in general also on a (factorization) scale of the hard process $\mu^2$. The elementary cross section in Eq. (2.1) can be written somewhat formally as:

$$d\hat{\sigma}_{gg \rightarrow Q\bar{Q}Q\bar{Q}} = \prod_{l=1}^{4} \frac{d^3p_l}{(2\pi)^3 2E_l} (2\pi)^4 \delta^4(\sum_{l=1}^{4} p_l - k_1 - k_2) \times \frac{1}{\text{flux}} |\mathcal{M}_{g^*g^* \rightarrow Q\bar{Q}Q\bar{Q}}(k_1, k_2)|^2,$$

where $E_l$ and $p_l$ are energies and momenta of final state heavy quarks. Above only dependence of the matrix element on four-vectors of incident partons $k_1$ and $k_2$ is made..
explicit. In general all four-momenta associated with partonic legs enter. The matrix element takes into account that both gluons entering the hard process are off-shell with virtualities \( k_1^2 = -k_{1i}^2 \) and \( k_2^2 = -k_{2i}^2 \). In numerical calculations we limit ourselves to the dominant gluon-gluon fusion channel of the \( 2 \rightarrow 4 \) type parton-level mechanism. We checked numerically that the channel induced by the \( q\bar{q} \)-annihilation can be safely neglected in the kinematical region under consideration here.

The off-shell matrix elements for higher final state parton multiplicities, at the tree-level are calculated analytically applying well defined Feynman rules [18] or recursive methods, like generalised BCFW recursion [19], or numerically with the help of methods of numerical BCFW recursion [20]. The latter method was already applied for \( 2 \rightarrow 3 \) production mechanisms in the case of \( c\bar{c} + \text{jet} \) [21] and even for \( 2 \rightarrow 4 \) processes in the case of \( c\bar{c}c\bar{c} \) [7], four-jet [22] and \( c\bar{c} + 2 \text{jets} \) [10] final states.

In this paper we use the same numerical methods. The calculation is performed with the help of KaTie [23], which is a complete Monte Carlo parton-level event generator for hadron scattering processes. It can be applied to any arbitrary processes within the Standard Model, for several final-state particles, and for any initial partonic state with on-shell or off-shell partons. The scattering amplitudes are calculated numerically as a function of the external four-momenta via Dyson-Schwinger recursion [24] generalized also to tree-level off-shell amplitudes. The phase space integration is done with the help of a Monte Carlo program with an adaptive phase space generator, previously incorporated as a part of the AVHLIB library [25, 26].

In the present calculation, we use \( \mu^2 = \sum_{i=1}^{4} m_{ii}^2 / 4 \) as the renormalization/factorization scale, where \( m_{ii} \)'s are the transverse masses of the outgoing heavy quarks. We take running \( \alpha_s \) at next-to-leading order (NLO), charm quark mass \( m_c = 1.5 \text{ GeV} \) and bottom quark mass \( m_b = 4.75 \text{ GeV} \). Uncertainties related to the choice of the parameters were discussed very recently in Ref. [10] and will be not considered here. We use the Kimber-Martin-Ryskin (KMR) [27, 28] unintegrated distributions for gluon calculated from the MMHT2014nlo PDFs [29]. The above choices are kept the same also in the case of double-parton scattering calculation except of the scales.

The effects of the \( c \rightarrow D^0 \) and \( b \rightarrow B^+ \) hadronization are taken into account via standard fragmentation function (FF) technique. We use the scale-independent Peterson model of FF [30] with \( \epsilon_c = 0.05 \) and \( \epsilon_b = 0.004 \) which is commonly used in the literature.
in the context of heavy quark fragmentation. Details of the fragmentation procedure together with discussion of the uncertainties related to the choice of the FF model can be found e.g. in Ref. [31]. In the last step, the cross section for meson is normalized by the relevant branching fractions \(\text{BR}(c \rightarrow D^0) = 0.565\) and \(\text{BR}(b \rightarrow B^+) = 0.4\).

### B. Double-parton scattering

A formal theory of multiple-parton scattering (see e.g. Refs. [32, 33]) is rather well established but still not fully applicable for phenomenological studies. In general, the DPS cross sections can be expressed in terms of the double parton distribution functions (dPDFs). However, the currently available models of the dPDFs are still rather at a preliminary stage. So far they are formulated only for gluon or for valence quarks and only in a leading-order framework which is for sure not sufficient for many processes, especially when heavy quark production is considered.

Instead of the general form, one usually follows the assumption of the factorization of the DPS cross section. Within the factorized ansatz, the dPDFs are taken in the following form:

\[
D_{1,2}(x_1, x_2, \mu) = f_1(x_1, \mu) f_2(x_2, \mu) \theta(1 - x_1 - x_2),
\]

where \(D_{1,2}(x_1, x_2, \mu)\) is the dPDF and \(f_i(x_i, \mu)\) are the standard single PDFs for the two generic partons in the same proton. The factor \(\theta(1 - x_1 - x_2)\) ensures that the sum of the two parton momenta does not exceed 1.

![A diagrammatic representation of the DPS mechanism for the pp → c\bar{c}b\bar{b} X (left panel) and for the pp → b\bar{b}b\bar{b} X (right panel) reactions.](image)

The differential cross section for \(pp \rightarrow Q\bar{Q}Q\bar{Q} X\) reaction within the DPS mechanism,
sketched in Fig. 2 can be then expressed as follows:

\[
\frac{d\sigma^{DPS}(QQ\bar{Q})}{d\xi_1 d\xi_2} = m \cdot \frac{d\sigma^{SPS}(gg \rightarrow QQ)}{d\xi_1} \cdot \frac{\sigma^{SPS}(gg \rightarrow QQ)}{d\xi_2},
\]

where \(\xi_1\) and \(\xi_2\) stand for generic phase space kinematical variables for the first and second scattering, respectively. The combinatorial factor \(m\) is equal 1 for \(cc\bar{c}\bar{b}\) and 0.5 for \(b\bar{b}b\bar{b}\) case. When integrating over kinematical variables one recovers the commonly used pocket-formula:

\[
\sigma^{DPS}(QQ\bar{Q}) = m \cdot \sigma^{SPS}(gg \rightarrow QQ) \cdot \frac{\sigma^{SPS}(gg \rightarrow QQ)}{\sigma_{eff}}.
\]

The effective cross section \(\sigma_{eff}\) provides normalization of the DPS cross section and can be roughly interpreted as a measure of the transverse correlation of the two partons inside the hadrons. The longitudinal parton-parton correlations are far less important when the energy of the collision is increased, due to the increase in the parton multiplicity. For small-\(x\) partons and for low and intermediate scales the possible longitudinal correlations can be safely neglected (see e.g. Ref. [34]). In this paper we use world-average value of \(\sigma_{eff} = 15\) mb provided by several experiments at Tevatron [35–37] and LHC [4, 38–41]. Future experiments may verify this value and establish a systematics.

There are several effects that may lead to a violation of the factorized ansatz (2.4), which seems a priori a severe approximation. The flavour, spin and color correlations lead, in principle, to interference effects that result in breaking the pocket-formula (see e.g. Refs. [32, 33]). In any case, the spin polarization of the two partons from one hadron can be mutually correlated, especially when the partons are relatively close in phase space (having comparable \(x\)'s). The two-parton distributions have a nontrivial color structure which also may lead to a non-negligible correlations effects. Such effects are usually not included in phenomenological analyses. They were exceptionally discussed in the context of double charm production [42] but in this case the corresponding effects were found to be very small. Moreover, including perturbative parton splitting mechanism [43–45] and/or imposing sum rules [46] also leads to a breaking of the pocket-formula. However, taken the above and looking forward to further improvements in this field, here we limit ourselves to a more pragmatic approach.

In our present analysis cross sections for each step of the DPS mechanism are calcu-
lated in the $k_T$-factorization approach, that is:

\[
\frac{d\sigma^{SPS}(pp \rightarrow QQ \times)}{dy_1 dy_2 dp_1 dp_2} = \frac{1}{16\pi^2 s^2} \int \frac{d^2k_{1t}}{\pi} \frac{d^2k_{2t}}{\pi} |M_{g^*g^* \rightarrow QQ}|^2 \times \delta^2 \left( k_{1t} + k_{2t} - p_{1t} - p_{2t} \right) F_g(x_1, k_{1t}, \mu^2) F_g(x_2, k_{2t}, \mu^2),
\]

\[
\frac{d\sigma^{SPS}(pp \rightarrow Q\bar{Q} \times)}{dy_3 dy_4 dp_3 dp_4} = \frac{1}{16\pi^2 s^2} \int \frac{d^2k_{3t}}{\pi} \frac{d^2k_{4t}}{\pi} |M_{g^*g^* \rightarrow Q\bar{Q}}|^2 \times \delta^2 \left( k_{3t} + k_{4t} - p_{3t} - p_{4t} \right) F_i(x_3, k_{3t}, \mu^2) F_j(x_4, k_{4t}, \mu^2).
\]

(2.6)

The numerical calculations for both SPS mechanisms are also done within the KaTie code, where the relevant fully gauge-invariant off-shell $2 \rightarrow 2$ matrix element $M_{g^*g^* \rightarrow QQ}$ is obtained numerically. Its useful analytical form can be found e.g. in Ref. [15]. Here, the strong coupling constant $\alpha_S$ and uGDFs are taken the same as in the case of the calculation of the SPS mechanism. The factorization and renormalization scales for the two single scatterings are $\mu^2 = \frac{m_{1t}^2 + m_{2t}^2}{2}$ for the first, and $\mu^2 = \frac{m_{3t}^2 + m_{4t}^2}{2}$ for the second subprocess.

III. NUMERICAL RESULTS

Let us start this section with presentation of results of our calculations for inclusive open bottom meson production. In Fig.3 we compare our theoretical predictions based on the $k_T$-factorization approach with the LHCb experimental data [47] at $\sqrt{s} = 7$ TeV. We get a very good agreement with the experimental points for both, the transverse momentum (left panel) and rapidity (right panel) $B^0$ meson distributions. Only the cross section in the lowest rapidity bin $y \in (2.0, 2.5)$ seems to be slightly overestimated, however the experimental uncertainties in this case are noticeably larger than in other rapidity intervals. Similar high-level agreement between the $k_T$-factorization predictions and experimental data has been also reported by us in the case of inclusive open charm meson production (see e.g. Ref. [48]). This approach was found to be very efficient also for more exclusive correlation observables [31, 49]. Having those conclusions in mind we expect that the chosen theoretical framework should provide a reliable predictions also for simultaneous production of charm and bottom as well as for double bottom production.
Now we go to the case of simultaneous production of charm and bottom particles. We start with the parton-level predictions for inclusive production of $c\bar{c}b\bar{b}$ final state at $\sqrt{s} = 13$ TeV. In Fig. 4 we show transverse momentum (top panels) and rapidity (bottom panels) distributions of charm (left panels) and bottom (right panels) quarks. The results are obtained for the full phase-space. The SPS (dotted histograms) and DPS (dashed histograms) contributions are shown separately. We observe that the DPS component significantly dominates over the SPS one in the whole rapidity range. It is also true for the transverse momentum distribution of bottom quark. In the case of charm quark the situation is slightly different. At small transverse momenta the DPS mechanism also gives dominant contribution, but both components become comparable when going to larger $p_T$'s.

The optimistic situation for searching for DPS effects in this channel presented above does not change when hadronization effects and kinematical cuts relevant for the LHCb experiment are taken into account. We consider inclusive production of $D^0B^+$-pair since this mode has the most advantageous $cb \to DB$ fragmentation probability and leads to the biggest cross sections. In Fig. 5 we show the transverse momentum distribution of $D^0$ (left panel) and $B^+$ (right panel) meson at $\sqrt{s} = 13$ TeV for the case of simultaneous $D^0B^+$-pair production in the LHCb fiducial volume defined as $2 < y < 4$ and $3 < p_T < 12$ GeV for both mesons. Again, the SPS (dotted lines) and the DPS (dashed...
FIG. 4: Transverse momentum (top) and rapidity (bottom) distributions of charm (left) and bottom (right) quark for the case of inclusive production of $c\bar{c}b\bar{b}$ final state. Contributions of the SPS (dotted) and the DPS (dashed) mechanisms are shown separately. The results are obtained within the $k_T$-factorization approach with the KMR uPDFs for $\sqrt{s} = 13$ TeV.

lines) components are shown separately, together with their sum (solid lines). Here, the conclusions are the same as for the parton-level results. We observe an evident enhancement of the cross section, at the level of order of magnitude, because of the presence of the DPS mechanism in the whole considered kinematical domain. We predict that the $D^0B^+$ data sample, that could be collected with the LHCb detector, should be DPS dominated in the pretty much the same way as in the case of double charm production (see e.g. Ref. [5]).

In Fig. 6 we present correlations observables that could be helpful in experimental identification of the predicted DPS effects. The characteristics of the di-meson invariant mass $M_{D^0B^+}$ (left panel) as well as of the azimuthal angle $\varphi_{D^0B^+}$ (right panel) dif-
FIG. 5: Transverse momentum distribution of $D^0$ (left) and $B^+$ (right) meson at $\sqrt{s} = 13$ TeV for the case of inclusive $D^0B^+$-pair production in the LHCb fiducial volume. The SPS (dotted) and the DPS (dashed) components are shown separately. The solid lines correspond to the sum of the two mechanisms under consideration. The results are obtained within the $k_T$-factorization approach with the KMR uPDFs.

Differential distributions is clearly determined by the large contribution of the DPS mechanism. We predict a significant enhancement of the cross section at small invariant masses $M_{D^0B^+} \lesssim 15$ GeV and a strong effect of azimuthal angle decorrelation, are related to the DPS mechanism.

FIG. 6: The same as in Fig. 5 but for the $D^0B^+$-pair invariant mass (left) and azimuthal angle $\phi_{D^0B^+}$ (right) distributions.

Similar conclusions about a possibility of experimental observation and exploration of the DPS effects can be also drawn for the case of double bottom production. As it is
shown in Fig. 7 the relation between the SPS and the DPS components for the $b$-quark transverse momentum (left panel) and rapidity (right panel) distribution in the case of $b\bar{b}b\bar{b}$ production is very similar to the relation predicted for the $c\bar{c}b\bar{b}$ final state (see right panels of Fig. 4). The main observed differences are the absolute normalization of the cross section, which is about order of magnitude smaller than in the case of $c\bar{c}b\bar{b}$, and a bit smaller relative contribution of DPS.

The predictions for $B^+B^+$ meson-meson pair production for the LHCb experiment only confirm the above statement. The effects related to the DPS mechanism on the $B^+$-meson transverse momentum (see Fig. 8), on di-meson invariant mass $M_{B^+B^+}$ and on relative azimuthal angle $\varphi_{B^+B^+}$ (see left and right panels of Fig. 9) distributions are pretty much the same as in the case of simultaneous production of charm and bottom.

To summarize the situation for the LHCb experiment, in Table I we collect the integrated cross sections for $D^0B^+$ and $B^+B^+$ meson-meson pair production in nanobarns within the relevant acceptance: $2 < y_{D^0B^+} < 4$ and $3 < p_{T,D^0B^+} < 12$ GeV. We predict quite large cross sections, in particular, at $\sqrt{s} = 7$ TeV the calculated cross section for $D^0B^+$ pair production is only 5 times smaller than the cross section already measured by the LHCb for $D^0D^0$ final state [4]. The cross sections for $B^+B^+$ are order of magnitude smaller than in the mixed charm-bottom mode, however, still seems measurable. In both
FIG. 8: Transverse momentum distribution of $B^+$ meson at $\sqrt{s} = 13$ TeV for the case of inclusive $B^+B^+$-pair production in the LHCb fiducial volume. The SPS (dotted) and the DPS (dashed) components are shown separately. The solid lines correspond to the sum of the two mechanisms under consideration. The results are obtained within the $k_T$-factorization approach with the KMR uPDFs.

FIG. 9: The same as in Fig. 8 but for the $B^+B^+$-pair invariant mass (left) and azimuthal angle $\phi_{B^+B^+}$ (right) distributions.

cases, the DPS component is the dominant one. The relative DPS contribution for both energies and for both experimental modes is at the very high level of 90%. This makes the possible measurements a very interesting from the point of view of the multi-parton interaction community.

Now we wish to present results of similar studies as presented above but for the CMS experiment. Here, the situation may be quite different than in the case of the LHCb experiment because of the quite different kinematical domains defined by the detector
TABLE I: The integrated cross sections for $D^0B^+$ and $B^+B^+$ meson-meson pair production (in nb) within the LHCb acceptance: $2 < y_{D^0,B^+} < 4$ and $3 < p_{T,D^0,B^+} < 12$ GeV, calculated in the $k_T$-factorization approach. The numbers include the charge conjugate states.

| Final state | Mechanism | $\sqrt{s} = 7$ TeV | $\sqrt{s} = 13$ TeV |
|-------------|-----------|---------------------|---------------------|
| $D^0B^+ + \bar{D}^0B^-$ | DPS       | 115.50              | 418.79              |
|              | SPS       | 21.13               | 51.46               |
| $B^+B^+ + B^-B^-$ | DPS       | 11.04               | 43.40               |
|              | SPS       | 1.31                | 3.39                |

acceptance in both experiments. The CMS experiment could collect the data for double bottom production in the region of $|y_{B^\pm}| < 2.2$ and $10 < p_{T,B^\pm} < 100$ GeV. Here, crucial is the lower cut on meson transverse momenta which is quite large (much larger than in the case of the LHCb). This may lead to damping of the relative DPS contribution to the cross section under consideration.

![Transverse momentum distribution of $B^+$ meson at $\sqrt{s} = 13$ TeV](image)

FIG. 10: Transverse momentum distribution of $B^+$ meson at $\sqrt{s} = 13$ TeV for the case of inclusive $B^+B^+$-pair production for the CMS detector acceptance. The SPS (dotted) and the DPS (dashed) components are shown separately. The solid lines correspond to the sum of the two mechanisms under consideration. The results are obtained within the $k_T$-factorization approach with the KMR uPDFs.

In Fig. 10 we show the differential cross section as a function of transverse momentum of $B^+$ meson for the CMS experiment at $\sqrt{s} = 13$ TeV. Here, the DPS mechanism dominates over the SPS one in the region of small transverse momenta $p_{T,B^+} \lesssim 20$ GeV,
TABLE II: The integrated cross sections for $B^+B^+$ meson-meson pair production (in nb) within the CMS acceptance: $|y_{B^+}| < 2.2$ and $10 < p_{T}^{B^+} < 100$ GeV, calculated in the $k_T$-factorization approach. The numbers include the charge conjugate states.

| Final state          | Mechanism | $\sqrt{s} = 7$ TeV | $\sqrt{s} = 13$ TeV |
|----------------------|-----------|---------------------|----------------------|
| $B^+B^+ + B^-B^-$    | DPS       | 6.84                | 26.27                |
|                      | SPS       | 7.24                | 17.05                |

however, the effect is not so strong as in the case of the LHCb experiment.

FIG. 11: The same as in Fig. 10 but for the $B^+B^+$-pair invariant mass (left) and azimuthal angle $\varphi_{B^+B^+}$ (right) distributions.

In Fig. 11 we show the relevant distributions in di-meson invariant mass $M_{B^+B^+}$ (left panel) and azimuthal angle $\varphi_{B^+B^+}$ (right panel). We observe a small effect of the enhancement of the cross section especially at small invariant masses $M_{B^+B^+} \lesssim 50$ GeV, related to the DPS mechanism. The azimuthal angle $\varphi_{B^+B^+}$ distribution may be the most helpful for experimental identification of the DPS component within the CMS detector, since we predict also in this case a significant decorrelation of the distribution.

Finally, in Table III we show predictions for the integrated cross section. The calculated cross sections for $B^+B^+$ production are very similar to those obtained for the LHCb detector, however, the relative DPS contribution for the CMS experiment is predicted at the level of 50% and 60% at $\sqrt{s} = 7$ and 13 TeV, respectively, i.e. smaller than in the case of LHCb.
IV. CONCLUSIONS

In our previous studies we discussed in detail production of $c\bar{c}c\bar{c}$ and $c\bar{c}+2\text{jets}$ final states in order to test and explore double-parton scattering effects. In general the processes with charm production and/or jets with small transverse momenta have large contribution of double-parton scatterings. Here we have tried to complete the first stage of exploration of DPS effects in the heavy flavour sector.

In the present paper we have extended our previous studies to simultaneous production of $c\bar{c}$ and $b\bar{b}$ and two pairs of $b\bar{b}$. It was our aim to understand the interplay of single- and double-scattering processes. The calculation have been done within the standard so far factorized ansatz with two independent partonic scatterings. The so-called $\sigma_{\text{eff}}$ parameter have been fixed at the same values as used in our previous studies for double charm production.

The cross section for each step has been calculated within the $k_T$-factorization approach including transverse momenta of gluons entering hard process. We have used the Kimber-Martin-Ryskin gluon distributions that turned out so succesful for production of charm. The hadronization of $c$ quarks to $D$ and $b$ quarks to $B$ mesons have been done with the help of phenomenological fragmentation functions. The Peterson fragmentation functions have been used. We have obtained good description of the LHCb data for $B^0 + \bar{B}^0$ production with our standard choice of factorization/renormalization scales.

Having shown that inclusive $B$ meson transverse momentum distributions are rather well understood $^1$ we have used our technique to calculate double parton scattering processes. The calculation of double parton scattering have been supplemented by calculation of single parton scattering ($2 \rightarrow 4$) processes using codes for automatized calculations of the off-shell matrix elements, i.e. including transverse momenta of initial gluons.

First we have explored several different differential distributions for $c\bar{c}b\bar{b}$ and $b\bar{b}b\bar{b}$ production for the whole phase space. We have observed clear dominance of the DPS over SPS for small transverse momenta of $c$ or $\bar{c}$ and in the broad range of transverse momenta of $b$ or $\bar{b}$.

---

$^1$ The same was shown previously for $D$ mesons.
Next we have considered distributions for simultaneous production of charmed and bottom mesons. The DPS mechanism have been shown to dominate for small invariant masses of the DB systems. We have predicted only a small decorrelation in relative azimuthal angle, typical for DPS dominance.

The situation for \( b\bar{b} b\bar{b} \) and two \( B^+ B^+ \) meson production is rather similar as for the mixed heavy flavour production, but here the dominance of the DPS over SPS is limited to smaller corners of the phase space. A good description of future data will therefore require to include both DPS and SPS mechanisms simultaneously. All the considered reactions should be easily measured as the corresponding cross sections are rather large.

A comment on possible in principle measurements is in order. Usually experimental subgroups specialize exclusively either in the production of \( D \) mesons or \( B \) mesons, simultaneous production of \( D \) and \( B \) mesons will require some coordination of the action of such different subgroups. In our opinion it would be a valuable effort. An experimental extraction of the \( \sigma_{\text{eff}} \) parameter for different reactions and a comparison for different processes studied here and in our previous papers would be a simple but necessary step to better understand double scattering in a more precise way. Also a compilation of the \( \sigma_{\text{eff}} \) would be important phenomenological knowledge. The factorized ansatz is an approximation and a possible deviations from it were discussed in the literature. Once such studies as discussed here are completed one can try to explore deviations from the simple approach. No clear deviations were found so far. The only exception is production of quarkonia pairs were very small values of \( \sigma_{\text{eff}} \) were extracted from experimental data. The situation in quarkonia pair production is however more complex. As discussed recently in Ref. [50] there are several single-parton mechanisms with DPS characteristics. Such processes were not considered so far in theoretical calculations so the extraction of \( \sigma_{\text{eff}} \) for these reactions is not reliable. Therefore in DPS studies one should concentrate first rather on processes with heavy quark/meson production.
