ABSTRACT

GRB 080913 and GRB 090423 are the most distant gamma-ray bursts (GRBs) known to-date, with spectroscopically determined redshifts of $z = 6.7$ and $z = 8.1$, respectively. The detection of bursts at this early epoch of the Universe significantly constrains the nature of GRBs and their progenitors. We perform population synthesis studies of the formation and evolution of early stars, and calculate the resulting formation rates of short and long-duration GRBs at high redshift. The peak of the GRB rate from Population II stars occurs at $z \sim 7$ for a model with efficient/fast mixing of metals, while it is found at $z \sim 3$ for an inefficient/slow metallicity evolution model. We show that in the redshift range $6 \lesssim z \lesssim 10$ essentially all GRBs originate from Population II stars, regardless of metallicity evolution model. These stars (having small, but non-zero metallicity) are the most likely progenitors for both long GRBs (collapsars) and short GRBs (NS-NS or BH-NS mergers) at this epoch. Although the predicted intrinsic rates of long and short GRBs are similar at these high redshifts, observational selection effects lead to higher (factor of $\sim 10$) observed rates for long GRBs. We conclude that the two recently observed high-$z$ GRB events are most likely long GRBs originating from Population II collapsars.

Subject headings: binaries: general—gamma rays: bursts—stars: formation

1. INTRODUCTION

The Swift satellite has recently discovered two high-redshift GRBs: GRB 080913 at redshift $z = 6.7$ (Schady et al. 2008), and GRB 090423 at redshift $z = 8.1$–8.3 (Tanvir et al. 2009, Salvaterra et al. 2009). The gamma-ray properties of these bursts straddle the traditional dividing lines between short and long bursts, making a solid classification of each burst difficult. For example, the observed burst duration of GRB 080913, $\sim 8$ s, classifies it as a long GRB (Stamatikos et al. 2008). However, in the rest frame of the burst the duration is $\sim 1$ s, suggesting a short GRB (Perez-Ramirez et al. 2008). It has been argued that, despite its relatively short duration (in the comoving frame), GRB 080913 nonetheless should be classified as a long GRB due to the specifics of the category definition (which places the dividing line at 2 s in the observer frame, for a GRB sample with mostly unknown redshifts), and because other properties of this burst (e.g., the lag-luminosity and Amati (2006) relations) are consistent with those of long GRBs (Greiner et al. 2008). Similarly, GRB 090423 had a burst duration of $\sim 9$ s, and a rest-frame duration of $\sim 1$ s. Unlike many of the gamma-ray diagnostics of this burst ($T_{90}$, $E_{\text{peak}}$, hardness ratio) would classify it as “short” had the burst occurred at low redshift, it has been argued that GRB 090423, as in the case of GRB 080913, is a “long” burst (Salvaterra et al. 2009; Zhang et al. 2009).

We employ two simplifications of nomenclature. First, we retain the use of the “short” and “long” classifications for GRBs, despite growing evidence that the classification should be determined using a broader set of criteria beyond merely burst duration (Donaghy et al. 2006; Zhang et al. 2007; Bloom et al. 2008). Second, we tie these two classifications to specific progenitors using the simple theory correspondences outlined in Popham et al. (1999). Long GRBs are believed to be associated with the deaths of massive stars, and the associated formation of black holes (e.g., Woosley 1993; Galama et al. 1998; Hjorth et al. 2003; Stanek et al. 2003; Woosley & Bloom 2006). Short GRBs, on the other hand, are thought to originate from the merger of compact objects, such as double neutron star (NS-NS) or black hole neutron star (BH-NS) binaries (e.g., Paczynski 1986; Eichler et al. 1989; Nakar 2007 and references therein). An alternative, unified model for GRBs has been proposed to simultaneously explain both long and short GRBs in terms of the same underlying physical mechanism, involving a black hole as central engine (e.g., Ruffini et al. 2006; Dar & Rujula 2004). In addition, there exist models for both short and long GRBs that do not involve black holes (e.g., Usov 1992; King, Olsson, & Davies 2007; Cheng & Dai 1996). A preferable classification of bursts might focus on the progenitor classification of each burst, which depends upon supernova association, host galaxy type, metallicity, and offset of the GRB with respect to the host galaxy (see Fryer et al. 2007 for a review). In this paper we study the progenitors directly, and identify collapsars with long GRBs, and compact object mergers with short GRBs.

Given their cosmological nature, and their bright afterglows, GRBs are unique tools to probe cosmological parameters and the structure and composition of matter along the GRB sightlines (e.g., Lamb & Reichart 2000;
Lloyd-Ronning et al. 2002; Gou et al. 2004; Prochaska et al., 2007; Lamb 2007; Hartmann 2008; Savaglio et al. 2008; Pirani et al. 2008; Hartmann et al. 2009). This argument gains force with the discovery of GRBs at very high redshifts; for example GRB 050904 at \(z = 6.29\) (Cusumano et al. 2006; Kawae et al. 2006), and now GRB 080913 and GRB 090423 beyond the furthest quasars (e.g., CFHQS J2329-0301 at \(z = 6.4\); Willott et al. 2007) and the furthest spectroscopically confirmed galaxies (galaxy IOK-J2329-0301 at \(z = 7.3\), Willott et al. 2007). These high redshift objects provide a unique opportunity to study the Universe during the extended, inhomogeneous epoch of reionization, tracing cosmic star formation back to the first generation of stars (Population III). GRB follow-up observations have the potential to reveal the fraction of neutral hydrogen and metal abundances as a function of redshift, possibly beyond \(z \sim 10\), with future instrumentation on large aperture telescopes on the ground and in space. GRBs constrain star formation models in the pristine Universe, and serve as unique light sources to pinpoint star formation activity even in the smallest proto-galaxies which would otherwise remain undetected. Rapid absorption spectroscopy of their afterglows offers a truly exceptional opportunity for studies of cosmic chemical evolution in an otherwise inaccessible part of the cosmic baryon field. However, in order to utilize these distant GRBs as probes, prompt localization and redshift determination is crucial. Currently, the Swift satellite performs rapid response observations in the X-ray and optical-UV bands. Future missions, such as the Energetic X-ray Imaging Survey Telescope (EXIST; Grindlay 2006), will provide combined wide-field X-ray and near-infrared imaging spectroscopy to study distant GRBs and associated black hole formation in the early Universe.

In this study we attempt to characterize the progenitors of GRB 080913 and GRB 090423, and other potential GRBs at these high redshifts. As we shall see, this epoch is entirely dominated by Population II stars and we focus on GRBs produced only from these stars. We analyze the formation of stars at high redshift in §2. In §3 we use a self-consistent model to follow in detail the evolution of the most likely GRB progenitors: massive stars and NS-NS/BH-NS mergers. In §4 we adopt a cosmological model to estimate the GRB intrinsic (§5) and observed (§6) event rates at high redshift, explicitly identifying the likely progenitors of GRB 080913 and 090423. We conclude in §7.

2. STELLAR POPULATIONS: MODEL/RESULTS

Star Formation History. To derive rates for various stellar events (supernovae, mergers, etc.) one must start from a star formation rate history, and add assumptions about the cosmic evolution of basic properties such as the Initial Mass Function (IMF) and the fraction of stars in binaries. We use the analytic cosmic star formation rate (SFR) prescription provided by Strolger et al. (2004):

\[
sfr(t) = 10^9a(t^b e^{-t/c} + dc(t-t_0)/c) M_\odot \text{ yr}^{-1} \text{ Gpc}^{-3},
\]

where \(t\) is the age of Universe (in Gyr) as measured in the global comoving (rest) frame, \(t_0\) is the present age of the Universe \((t_0 = 13.47\ \text{Gyr}; \text{see } \S 4)\), and we adopt parameters corresponding to the extinction-corrected model: \(a = 0.182, b = 1.26, c = 1.865, d = 0.071\). The SFR rate density described above is in comoving units (space as well as time); for a non-evolving population, this rate is constant.

Galaxy Mass Distribution. At redshift \(z < 4\) we describe the distribution of galaxy masses using a Schechter-type probability density function, calibrated to observations from Fontana et al. (2006):

\[
\Phi(M_{\text{gal}}, z) = \Phi^*(z) \int (10)^{1+a(z)\epsilon} e^{-a}
\]

with \(\Phi^* = 0.0035(1+z)^{-2.20}, a = 10^{\log(M_{\text{gal}})-M_z}, M_z = 11.16+0.17z-0.07z^2, \text{ and } a(z) = -1.18-0.082z\). A galaxy mass, \(M_{\text{gal}}\), in units of \(M_\odot\), is drawn from this distribution (Eq. 2) in the range \(7 < \log(M_{\text{gal}}) < 12\). For galaxies at redshifts beyond \(z = 4\) we use the above distribution evaluated at \(z = 4\), i.e., we assume no evolution in the galaxy mass distribution at earlier times. This assumption reflects the lack of information on galaxy mass distributions at high redshift. Although this may be a decent approximation at intermediate redshifts \((4 < z < 10)\), it is almost certainly incorrect at very high redshift, where only low mass galaxies (and Population III stars) are forming.

Galaxy Metallicity. We assume that the average oxygen to hydrogen number ratio \((F_{\text{OH}})\) of a typical galaxy depends on its mass as:

\[
\log(F_{\text{OH}}) = \log(10^{13.5} / \text{H}) = sz + 1.847 \log(M_{\text{gal}}) - 0.08026(\log(M_{\text{gal}}))^2
\]

with a redshift independent normalization \(sz = -1.492\) (Tremonti et al. 2004). It has been suggested that the functional form of this mass-metallicity relation is redshift independent (Erb et al. 2006; Young & Fryer 2007), with only the normalization factor, \(sz\), varying with redshift. We characterize the redshift dependence of galaxy metallicities using the average metallicity relation from Pei, Fall, & Hauser (1999):

\[
Z \propto \begin{cases} 10^{-a_2}\quad & z < 3.2 \\ 10^{-b_1-b_2z}\quad & 3.2 \leq z < 5 \\ 10^{-c_1-c_2z}\quad & z \geq 5 \end{cases}
\]

which implies evolution of the normalizing factor, \(sz\), with redshift given by

\[
sz \propto \begin{cases} -a_2z - 1.492\quad & z < 3.2 \\ -b_2z - 3.2(a_2-b_2) - 1.492\quad & 3.2 \leq z < 5 \\ -c_2z - 5(b_2-c_2) - 3.2(a_2-b_2) - 1.492\quad & z \geq 5 \end{cases}
\]

With this approach we assume that the oxygen abundance (used in \(F_{\text{OH}}\)) correlates linearly with the average abundance of elements heavier than Helium (which is what is provided in the metallicity measure, \(Z\)). The normalization given by Pei et al. (1999) is \(a_2 = 0.5, b_1 = 0.8, b_2 = 0.25, c_1 = 0.2, c_2 = 0.4\). We also derive the coefficients from the metallicity dependence proposed by Young & Fryer (2007), based on ultraviolet (GALEX, Sloan Digital Sky Survey), infrared (Spitzer), and neutrino (Super-Kamiokande) observations (Hopkins & Beacom 2006): \(a_2 = 0.12, b_1 = -0.704, b_2 = 0.34, c_1 = 0.0, c_2 = 0.1992\). The Pei et al. (1999) normalization results in a relatively slow metallicity evolution as compared with the model of Young & Fryer (2007), which allows for a rapid increase of the average metallicity of stars with
time. This is shown in Figure 1 (top panel), which provides the metallicity distribution of stars. It is apparent that for the fast model the metallicity of stars is on average an order of magnitude higher than for the slow model at the same high \((z = 7)\) redshift.

Using Equations 3 and 5 we estimate the average galaxy oxygen to hydrogen ratio, given the mass and redshift of a galaxy. We express our estimators relative to solar:

\[
F_{\text{OH,gal}} = F_{\text{OH}}/F_{\text{OH,\odot}},
\]

where \(F_{\text{OH,\odot}} = 4.9 \times 10^8\) is the solar value (Tremonti et al. 2004).

**Galaxy Stellar Population.** We use the above galaxy metallicity estimator to formally delineate different stellar populations:

\[
\begin{align*}
F_{\text{OH,gal}} &< 10^{-4} & \text{Population III} \\
10^{-4} &\leq F_{\text{OH,gal}} &\leq 10^{-1} & \text{Population II} \\
F_{\text{OH,gal}} &> 10^{-1} & \text{Population I}
\end{align*}
\]

Our choice for the lower metallicity bound \((10^{-4})\) on Population II marks the point where metals are abundant enough to provide sufficient cooling in the collapse of gas clouds, and thus star formation significantly deviates from the Population III stage (e.g., Mackey, Bromm, & Hernquist 2003; Smith et al. 2008). It also marks the point where winds of massive stars are sufficiently strong to prevent the formation of pair-instability supernovae (Heger et al. 2003). The choice for the Population II upper bound is dictated by the observation of Population I and II stars in the Milky Way (e.g., Binney & Merrifield 1998; Beers & Christlieb 2005). Population I stars (e.g., disk and bulge stars) have metallicities that are approximately solar, with variations of a factor of five. Population II stars (e.g., halo populations, such as stars in globular clusters) have metallicities at or below \(10^{-1}-10^{-2}\) solar.

Each galaxy is assumed to host just one stellar population, determined by its metallicity. Since we draw a large number of galaxies at any given redshift (see Eq. 2) via Monte Carlo simulations, the use of an average metallicity measure is appropriate.

In Figure 1 (bottom panel) we show our assumed star formation history as a function of redshift, with the contribution from Population II stars highlighted. Population II stars form over a wide range of redshifts, starting at \(z \approx 22\), and peaking at \(z \approx 7\) for the fast metallicity evolution model. For the slow metallicity evolution, the interstellar medium is enhanced with metals much later, and Population II stars begin forming only at redshifts \(z \sim 11\), peaking at \(z \sim 3\). Although the metallicity evolution is poorly constrained, the two adopted models are most likely extremes, with the true evolution somewhere in between. For example, the transition from Population III to Population II stars is found to occur at \(z \sim 11\) and \(z \approx 22\) for our slow and fast metallicity evolution models, respectively. More sophisticated models place this limit at redshifts \(z \sim 15-20\) (e.g., Mackey et al. 2003).

Recent results show that Population III stars can form as recently as \(z \approx 5\) (Schneider et al. 2006; Tornatore, Ferrara, Schneider 2007), but with rates significantly below that of Population II stars.

Population III stars were forming prior to the measured redshifts of GRB 080913 and 090423. Individual Population III stars may give rise to long GRBs in collapsar models with enhanced rotation (e.g., Yoon, Langer, & Norman 2006). However, as the lifetime of massive Population III stars is very short \((\sim 3-6\text{ Myr})\), for G.S. Schaerer (2002), these GRBs would be observed at much higher redshifts \((z \gtrsim 10)\), tracing the Population III star formation rate with little delay. If binary Population III stars are formed, they could evolve into NS-NS/BH-NS systems that in turn, after an appropriate delay before merging, would give rise to short GRBs at potentially much lower redshift (although see Ripamonti & Abel 2004 and O'Shea & Norman 2007, both of whom find that fragmentation does not occur in pristine clouds, implying that no Population III binaries would form). It has been argued that GRBs from such binaries, if they do form, would result in negligible detection rates for current detectors, including Swift (Belczynski et al. 2007).

The transition from Population II to Population I star formation begins at \(z \sim 7\) for the fast or at \(z \sim 3\) for the slow metallicity evolution model, continuing gradually until the present. Regardless of the metallicity evolution model, Population I stars are the dominant contribution to the star formation rate below \(z \sim 2\), although a small number of Population II stars are also predicted at these lower redshifts. The earliest Population I stars begin forming at \(z \sim 7\), but this is a negligible fraction of the total star formation at this redshift, even for the extreme fast metallicity evolution model (see Fig. 1 top panel). Significant formation of Population I stars is found for redshifts \(z \lesssim 6\) (fast) and \(z \lesssim 2.5\) (slow), and thus Population I stars are unlikely to be the progenitors of high-\(z\) bursts.

Regardless of metallicity evolution models, Population II stars dominate the star formation rate at redshift \(6 \lesssim z \lesssim 10\) (see Fig. 1), and are the likely progenitors for both GRB 080913 and GRB 090423. Therefore, in the following we focus exclusively on Population II stars.

3. STELLAR EVOLUTION: MODEL/RESULTS

**Evolutionary Code.** We use the StarTrack population synthesis code (Belczynski et al. 2002, 2008a), which employs the stellar evolution models of Hurley, Pols, & Tout (2000), to calculate the population of low metallicity stars, with the mass of the primary (the initially more massive) member, \(M_1\), drawn from a power-law initial mass function (IMF) with exponent \(-2.7\) in the range \(5-150\text{ M}_\odot\). The secondary member’s mass, \(M_2\), is drawn randomly from a uniform initial mass ratio distribution \((q = M_2/M_1 \in 0-1)\), where we only evolve binaries that have secondaries with \(M_2 > 3\text{ M}_\odot\). Initial orbital separations, \(a\), are drawn from a uniform random distribution in \(\ln a\) (i.e., \(pdf \propto 1/a\); Abt 1983), and eccentricities are taken from the distribution \(pdf = 2e\) (e.g., Heggie 1975; Duquennoy & Mayor 1991).

We also evolve a population of \(N_{\text{bin}} = 2 \times 10^6\) massive single stars, with initial masses chosen as described above for the primary members of the binaries. The lower mass limits are chosen such that all stars that can potentially form either neutron stars or black holes are included in the calculations.
If the mass range is extended to the hydrogen-burning limit (∼ 0.08 M⊙), one can estimate the total stellar mass that corresponds to our calculation (i.e., we evolve only the fraction of mass that is formed in massive stars, but for the purpose of rate calculations we also estimate the total stellar mass). We use a 3-component power law IMF; for stars with masses 0.08–0.5 M⊙ the exponent is −1.3, for stars in the mass range 0.5–1 M⊙ we use −2.2, and for masses above 1 M⊙ we use −2.7 (Kroupa, Tout, & Gilmore 1993; Kroupa & Weidner 2003). Note that our population assumes an equal number of single and binary star systems, corresponding to a binary fraction fbin = 50% (or a binary system membership probability of 2/3 for any randomly selected star). Spectroscopic studies demonstrate that binary fractions are significant, especially for massive stellar populations (e.g., ≥ 70% for the Westerlund-1 cluster (Clark et al. 2008), or ≥ 50% for NGC6231 (Sana et al. 2008)). The total mass in our simulation, in single and binary stars over the entire mass range, is Msim = 6.1 × 10^6 M⊙.

Short GRBs. We extract from the population synthesis sample the NS-NS and BH-NS binaries with delay times shorter than 15 Gyr. The total number of short GRB progenitors is found to be nshort = 7.6 × 10^6 with 4.6 × 10^6 NS-NS and 3.0 × 10^6 BH-NS systems. The delay time, tdel, is the time a given binary takes from the zero age main sequence to form a double compact object (evolutionary time, tcool) plus the time a double compact object takes to merge due to emission of gravitational radiation (merger time, tmerge). The resulting delay time distribution is shown in Figure 2. The median delay time is 0.1 Gyr, with a mean of 1.5 Gyr and a standard deviation of 2.9 Gyr. Contrary to conventional wisdom, most mergers are expected shortly after the stars form, with only a small fraction (3.7%) of delay times in excess of 10 Gyr (qualitatively similar results for Population I stars were presented in Bélierzynski et al. 2006).

Long GRBs. We extract black holes (formed in both isolated stars and in binaries) that (i) formed through direct collapse (e.g., Fryer & Kalogera 2001) and (ii) formed from a progenitor that at the time of core collapse was hydrogen depleted. The first condition ensures rapid accretion (∼ 0.1 – 1 M⊙ s−1) onto a black hole. Popham et al. (1999) found that at least some of the power sources for GRBs are much more efficient at higher accretion rates, and Young & Fryer (2007) argue that current observations are better fit by these direct-collapse black holes. For the adopted Population II metallicity, single stars with initial mass Mzams > 23.8 M⊙ form black holes through direct collapse. Note that the limiting mass was 40.0 M⊙ for solar metallicity, as obtained in Fryer & Kalogera (2001). Here we use different evolutionary models (Hurley et al. 2000) and we employ stellar winds that scale with metallicity as ∝ Z^1/2, and find that stars with lower mass can potentially form black holes directly. However, we note that had we used 40.0 M⊙ as a limiting mass for direct black hole formation, our predicted rates for long GRBs would have remained virtually the same since condition (ii) selects stars with mass that are above or close to the previous limit (see below). Our limit, which takes into account the effect of metallicity and stellar winds, is further modified by the presence of a binary companion (from rejuvenation and/or mass loss in close binaries).

The second condition allows for a GRB jet to punch through the outer layers of a star. A star may lose its H-rich envelope either through binary interactions or via stellar winds. Given the employed single star models, and the adopted metallicity, stars with Mzams > 35.9 M⊙ lose their entire H-rich envelopes via stellar winds. Binary interactions, on the other hand, may remove the envelope of a star of arbitrary mass. These conditions are insufficient to produce a GRB, since there must be just enough angular momentum in a collapsing star to form a lasting accretion torus (e.g., MacFadyen & Woosley 1999; Podsiadlowski et al. 2004). As angular momentum transport is not taken into account in this study, our predictions only indicate potential long GRB progenitors, i.e. most likely only a (small) fraction of the events that satisfy (i) and (ii) will actually produce long GRBs.

The total number of long GRB progenitors is found to be nlong = 225 × 10^5 with 103 × 10^5 and 122 × 10^5 direct black holes (DBHs) from H-depleted progenitors from single and binary stars, respectively. The delay time distribution is displayed in Figure 2. This represents the evolutionary time (tcool) of a given star to form a black hole. The delay times for long GRB progenitors are very short, ~ 3.5–12 Myr (as black holes form from massive and short-lived stars), with the median of the distribution at 5.1 Myr, a mean at 5.3 Myr, and a standard deviation of 1.1 Myr. These events thus trail the star formation rate, SFR(z), with very little delay, so that essentially one can assume that Rate(DBH) ∝ SFR until very large redshifts.

4. Cosmology: Model

We adopt a flat cosmology with H_0 = 70.0 km s\(^{-1}\) Mpc\(^{-1}\), Ω_m = 0.3, and Ω_Λ = 0.7 (and thus Ω_k = 0). Small (≤ 10%) changes in the cosmological parameters leave our results essentially unaltered.

For clarity in what follows, we briefly review the relevant cosmological expressions. The relationship between redshift and time is given by

\[ t(z) = t_H \int_z^\infty \frac{dz'}{(1 + z')E(z')} \]  

where t_H = 1/H_0 = 14 Gyr is the Hubble time (e.g., Hogg 2000), and \( E(z) = \sqrt{\Omega_M (1 + z)^3 + \Omega_K (1 + z)^2 + \Omega_\Lambda} \). The resulting age of the Universe is t(0) = 13.47 Gyr. It is to be noted that this is the restframe time, constituting what is measured by the wristwatches of local observers at any time and place in the Universe, and thus is the appropriate quantity to use when discussing local physical processes. Observed event rates from sources distributed over cosmic time must be corrected for time dilation, R(t) = R(z)/(1 + z).

The comoving volume element, dV/dz, for a given solid angle, dΩ, is given by

\[ \frac{dV}{dz}(z) = \frac{c}{H_0 E(z)} d\Omega, \]  

where c is the speed of light in vacuum, and where the comoving distance, D_c, is given by

\[ D_c(z) = \frac{c}{H_0} \int_0^z \frac{dz'}{E(z')}. \]  

There are a number of steps necessary to calculate the expected GRB event rates. To summarize: for each bin in time, we estimate the total star formation rate. We then calculate the fraction of these stars which are Population II by incorporating the metallicity distribution of the galaxies at the given time. We then employ population II synthesis results to determine the fraction of Population II stars that are progenitors of GRBs. With these results, we are able to apply the appropriate delay times and transform the progenitor formation rate in each bin in time to an actual GRB event rate, distributed over later times. We repeat this procedure over all bins in time, which results in a total GRB event rate as a function of time. We now go through each of these steps in detail.

We bin time over the range $0.13 < t < 13.47$ Gyr ($0 < z < 25$), with a constant width of $dt = 10$ Myr. For each bin we obtain the star formation rate using Equation\textsuperscript{1} evaluated at the center of the bin. We then generate a Monte Carlo sample of $10^4$ galaxies in the bin, distributed according to Equation\textsuperscript{2} with a total mass in galaxies given by $M_{\text{gal, tot}}$. For each galaxy we estimate its average metallicity from Equation\textsuperscript{3} and, based on our population criterion (Eq. 7), we determine the number of galaxies containing Population II stars. The total mass of galaxies with Population II stars is denoted $M_{\text{gal, II}}$. The fraction of mass that has formed Population II stars in a given bin is thus given by

$$F_{\text{pop, II}} = \frac{M_{\text{gal, II}}}{M_{\text{gal, tot}}},$$

since we have assumed that each galaxy hosts only one stellar population (determined by its average metallicity; see §2).

We measure rate densities in units of yr$^{-1}$ Gpc$^{-3}$, in comoving units (time and space). In our scheme a delay for a given event constitutes a shift in time of the relevant fraction of the rate density (see Eq. 12). The population synthesis results yield a list of Population II GRB progenitors, and their corresponding delay times, and we use all of them in each time bin. Thus, for each bin we have a total of $n_{\text{short}} = 7.6 \times 10^3$ and $n_{\text{long}} = 225 \times 10^3$ progenitors for short and long GRBs, respectively. Each progenitor in our list now represents a fraction of the total star formation rate density in the given bin that generates GRBs. This fraction is given by:

$$f_{\text{sim}} = \frac{F_{\text{pop, II}}}{M_{\text{sim}}} \text{sfr}(t),$$

where $M_{\text{sim}}$ is the total stellar mass corresponding to our population synthesis simulations (see §3), and $f_{\text{sim}}$ has units of yr$^{-1}$ Gpc$^{-3}$.

For each progenitor in the list we choose a random starting time, $t_0$, within the given time bin, and propagate the progenitor formation rate density, $f_{\text{sim}}$, forward in time to

$$t_{\text{new}} = t_0 + t_{\text{del}}.$$  

The delay time, $t_{\text{del}}$, marks the time elapsed from the formation of the star to the potential GRB event, as described in §3, and $t_{\text{new}}$ is the time at which a given GRB event actually occurs. We thus convert the formation rate density of progenitors into GRB event rate densities. By repeating the above series of steps for each time bin, we arrive at a total comoving GRB event rate density, $n_{\text{rest}}(t)$.

5. INTRINSIC RATES

In this section we calculate the intrinsic rate of short and long GRBs from Population II progenitors. In the first subsection we discuss correction factors due to model uncertainties, while in the second subsection we provide estimates of the intrinsic GRB rates.

5.1. Correction factors: population synthesis

Both the direct black hole formation and double compact object merger rates obtained from population synthesis are only first-order approximations for long and short duration GRBs, respectively. For example, the only constraints placed on our long-duration GRB progenitors were the assumption that the black hole formed from direct collapse and that the star, at collapse, was a He star. Observations of nearby GRB/SN associations suggest that the progenitor must lose most of its Helium, because, to date, every supernova observed associated with a GRB is a type Ic supernova (see Fryer et al. 2007 for a recent review). We have not placed additional constraints requiring the loss of the He envelope. In addition, we have not placed constraints on the angular momentum profile, which is likely to play an important role in GRB formation.

The type Ic constraint poses a problem for many of the current progenitor scenarios and, hence, makes it difficult to predict a reliable rate from population synthesis studies alone. Ignoring this constraint, we can make only rudimentary estimates of the GRB event rates. With the rotation rates suggested by Yoon et al. (2006), roughly 10% of the collapsing stars in our simulations form GRBs. Given our rate estimates for both long and short bursts, this indicates that the odds are roughly 10 to 1 that GRB 080913 and 090423 were long-duration bursts. However, Podsiadlowski et al. (2004) have argued that only 1% of all black hole systems would form GRBs. Although these authors mention that this fraction could potentially increase at low metallicity, if we keep their 1% figure we find a long-duration GRB rate 100 times smaller than the one we calculated for the direct black hole formation channel. Thus, the likely rate for long-duration GRBs is reduced by a factor of $\epsilon_{\text{syn, long}} \sim 0.01$.

Our rate for short GRBs is also an over-estimate. We include all BH-NS mergers, while neglecting system configuration (inclination/mass ratio) and black hole spin (only 1–40% percent of mergers are expected to form BH torus configurations and thus potentially result in a GRB: Belczynski et al. 2008b). If GRBs indeed require the formation of a black hole (e.g., Janka & Ruffert 1996; Oechslin & Janka 2006; Lee & Ramirez-Ruiz 2007), the fraction of NS-NS mergers is limited by the maximum neutron star mass. Most known NS-NS mergers will form central compact objects with masses $M_c \lesssim 2.5 M_\odot$ (Belczynski et al. 2008c). The maximum neutron star mass must be less than this value, or these mergers will not form black hole accretion disks. However, the requirement of a black hole is a weak constraint as neutron star accretion disks as well as proto-magnetars may also produce short GRBs (Usan 1992; Khuziak & Ruderman 1998; Dai et al. 2006; M}
The low metallicity population of double compact objects consists of \( \sim 60\% \) of NS-NS binaries and \( \sim 40\% \) of BH-NS systems (see §3). Thus the reduction due to the required configuration of BH-NS systems does not lead to a significant decrease of short GRB rates. The likely rate for short-duration GRBs is thus reduced by approximately \( \epsilon_{\text{syn,short}} \sim 0.6-0.8 \).

Additionally, the formation rates of double compact objects as calculated in population synthesis are subject to uncertainties that are associated with some poorly understood evolutionary processes that are important in the evolution of massive binaries (e.g., winds, mass transfer episodes, natal kicks). Belczynski et al. (2002) presented a comprehensive parameter study of double compact object formation rates. If the most unrealistic and unphysical models are omitted, it was shown that NS-NS and BH-NS merger rates vary at most by factor of \( \sim 6 \) (up and down) from the reference model (best guess for evolutionary parameters) value. We use this as an estimate of the population synthesis uncertainty in the rates and thus renormalize correction factors to \( \epsilon_{\text{syn,short}} \sim 0.1-4.8 \).

In summary, the population synthesis or model related correction factors are

\[
\begin{align*}
\epsilon_{\text{syn,long}} & = 0.01-0.1 \\
\epsilon_{\text{syn,short}} & = 0.1-4.8.
\end{align*}
\]

5.2. Intrinsic rate estimate

Our estimate of the intrinsic GRB event rate density in the rest frame is given by

\[
N_{\text{rest}}(t) = \epsilon_{\text{syn}} n_{\text{rest}}(t) \, \text{yr}^{-1} \, \text{Gpc}^{-3},
\]

where \( \epsilon_{\text{syn}} \) was introduced in the previous subsection, and \( n_{\text{rest}} \) was introduced in §4. The rate density of GRBs that would be observed is appropriately time dilated: \( \mathcal{N}_{\text{obs}}(t) = N_{\text{rest}}(t)/(1 + z(t)) \). In a slightly confusing accident of notation, the units of both of these quantities is \( \text{yr}^{-1} \, \text{Gpc}^{-3} \), where in one case years are measured in the rest frame of the GRB population, and in the other case years are measured by a clock at the local observatory.

It is to be noted that some events have such long delay times, or are associated with such recent star formation, that the GRB events will happen in our future \( (t_{\text{new}} > 13.47 \, \text{Gyr}) \), and thus are not included in the event rate density estimates. We note that this affects only short GRB progenitors, as delay times for long GRB progenitors are very short (see Fig. [2]).

We are also interested in the intrinsic GRB event rate, in addition to the event rate density. We present intrinsic event rates in the observer frame. To determine the rate to some specified redshift, \( z \), we integrate the GRB event rate density (modified by time dilation) over the comoving volume:

\[
N(<z) = 4\pi \epsilon_{\text{syn}} \int_0^z \frac{n_{\text{rest}} \, dV}{1 + z' \, dz'} \, dz' \, \text{yr}^{-1},
\]

where we have integrated over the entire sky \( (f d\Omega = 4\pi) \). It is important to note that, although the above integral is in redshift, it is integrating out the volume (given by Eq. [2]), and not the time: the original units of rate density (\( \text{yr}^{-1} \, \text{Gpc}^{-3} \)) have been converted into a rate (\( \text{yr}^{-1} \)) and not into a density (\( \text{Gpc}^{-3} \)). \( N(<z) \) represents the rate in the observer frame of all GRB events (bursts per year) integrating to a limiting redshift of \( z \). Since \( N \) denotes the intrinsic rate, we have not yet applied observational selection effects due to such things as beaming, brightness, or instrumental response (these are calculated in §6.1).

The population synthesis code naturally distinguishes between long and short GRBs, and we carry this identification through our calculations, quoting results for both long \( (N_{\text{long}}) \) and short \( (N_{\text{short}}) \) GRBs. The resulting intrinsic GRB rate densities and event rates are shown in Figures 3, 4, and 5. As expected for long GRBs, these rates closely track the star formation history of Population II stars: the majority (90%) of events are found at redshifts \( z \sim 3-15 \) with a peak at \( z \sim 7 \) (fast metallicity evolution model), or at \( z \sim 2-11 \) with a peak at \( z \sim 3 \) (slow model). Short Population II GRBs start appearing slightly later than long Population II GRBs, and their distribution extends to lower redshift \( (z \sim 0) \). However, the peak of the short GRB rate is near the long burst peak, at \( z \sim 7 \) (fast) and \( z \sim 3 \) (slow), due to the large abundance of very short delays. We note that even a delay as short as 0.1 Gyr is sufficient to result in a many kpc distance between the site of star formation in the host galaxy and the eventual merger location in the halo (e.g., Fryer, Woosley, & Hartmann 1999; Bloom, Sigurdsson, & Pols 1999; Belczynski et al. 2006). The short GRB progenitors considered here (NS-NS/BH-NS mergers) have a tail of very long delay times (median 0.1 Gyr, and standard deviation 2.9 Gyr), resulting in substantial intrinsic rates of Population II mergers at low redshift.

We note that in the redshift range \( 6 < z < 8 \), the intrinsic rates for long and short GRBs are comparable (see Fig. 6). At redshift \( z = 6.7 \), the rates are \( N_{\text{long}} = 10 \times 10^{-3}-153 \times 10^{-3} \, \text{yr}^{-1} \) and \( N_{\text{short}} = 3 \times 10^{-3}-141 \times 10^{-3} \, \text{yr}^{-1} \) per unit redshift, in the observer frame. At redshift \( z = 8.1 \) these rates become \( N_{\text{long}} = 9 \times 10^{-3}-91 \times 10^{-3} \, \text{yr}^{-1} \) and \( N_{\text{short}} = 2 \times 10^{-3}-84 \times 10^{-3} \, \text{yr}^{-1} \) (the ranges encompass both of our metallicity evolution models). The above similarity of rates arises for two reasons: first, the population synthesis rates of short \( (\epsilon_{\text{syn,short}} n_{\text{short}}) = 0.8 \times 10^{-3}-36.5 \times 10^{-3} \) and long \( (\epsilon_{\text{syn,long}} n_{\text{long}}) = 2.3 \times 10^{-3}-22.5 \times 10^{-3} \) GRB progenitors are comparable; second, Population II star formation rates for the two metallicity evolution models are almost the same \( (\sim 0.1 M_{\odot} \, \text{yr}^{-1} \, \text{Mpc}^{-3}) \); see Fig. 4] at these redshifts.

For comparison, we have also calculated the rate of supernovae utilizing the same procedure presented above. The cumulative rate of core collapse supernovae (Type II and Ib/c) is estimated to be \( \sim 8 \, \text{s}^{-1} \) (integrated to redshift \( z = 10 \)), which is comparable to the rates from recent empirical estimates of SFR(z), e.g. Hopkins and Beacom (2006).

6. Observed Rates

In this section we predict the Swift detection rate of short and long GRBs from Population II progenitors. In the first subsection we discuss observational selection effects, while in the second subsection we provide estimates of the observed GRB rates.
6.1. Correction factors: observational selection effects

Not all high-redshift GRBs will necessarily be observable. There are many factors which impact whether or not a given GRB will be observed, including the lightcurve and spectral energy distribution of the burst (both of them redshifted), as well as the spectral and time sensitivity of the detector. A precise calculation of the selection function of GRBs is well beyond the scope of this paper. The GRB population is tremendously heterogeneous, and the triggering algorithms of an instrument such as the BAT on Swift are highly complex (Band 2003, 2006; Fenimore et al. 2004). In what follows we make a number of simplifications, and derive an approximation for the observed rate of short and long GRBs.

We assume that all GRBs have the same distribution of average isotropic luminosity, $L_{\text{iso}}$, given by a Gaussian in $\log(L_{\text{iso}})$, centered on $L_{\text{iso}} = 10^{50}$ erg s$^{-1}$, with $\sigma = 1$ dex. We assume all short GRBs have a duration of $t_{90} = 0.5$ s, while all long GRBs last $t_{90} = 30$ s. The distributions of total energy (integrated flux; calculated as $E = L_{\text{iso}} t_{90}$) for short and long bursts are presented in Figure 6.

We approximate the Swift GRB trigger (for the BAT instrument) as a fluence threshold. We take the long GRB trigger as $E_{\text{long}} = 3 \times 10^{50}$ erg for a long burst at $z = 1$ (see, e.g., Fig. 2 of Kistler et al. 2008 and Fig. 2 of Butler et al. 2007). In other words, a long GRB at $z = 1$ must emit a total isotropic-equivalent energy satisfying $E \geq 3 \times 10^{50}$ erg to be observable. The corresponding short GRB threshold is given by $E_{\text{short}} = 10^{50}$ erg at $z = 1$. The difference between the thresholds is chosen to mimic some of the complexity in the BAT triggers, including integration and readout times, as well as sensitivity to the differing spectral energy distributions (SEDs) of long and short bursts (Fenimore et al. 2004; Band 2003, 2006). For a burst at redshift $z$, we draw an energy from the relevant distribution shown in Figure 6, and then calculate whether the fluence of the burst satisfies our trigger threshold criterion:

$$E \geq (D_L(z)/D_L(z=1))^2 \tilde{E},$$

where $D_L(z)$ is the luminosity distance out to redshift $z$. Only those bursts which satisfy this inequality are taken to be observed. The resulting fraction of long and short bursts observed with Swift, $\epsilon_{\text{SED}}$, as a function of redshift, is plotted in Figure 6.

Another factor we have not yet considered is beaming, and the resulting visibility of GRBs. In general short GRB jets appear to be wider, with opening angles of $\Theta \gtrsim 10^\circ$ (e.g., Fox et al. 2005; Berger 2007; Metzger, Piro, & Quataert 2008) as compared with long GRBs, $\Theta \sim 5^\circ$ (e.g., Frail et al. 2001; Bloom, Frail, & Kulkarni 2003; Grupe et al. 2006; Soderberg et al. 2006). This would imply that long GRBs are $\sim 4$ times less likely to be detected, leading to further reduction of the observed rates by factors of

$$\epsilon_{\text{beam, long}} = 0.002$$  \hspace{1cm} (19)

$$\epsilon_{\text{beam, short}} = 0.008$$  \hspace{1cm} (20)

for long and short GRBs, respectively.

6.2. Observed rate estimate

We now provide a prediction for the Swift detection rate for Population II GRBs. We express rates per unit redshift to emphasize the redshift range relevant for GRB 080913 and GRB 090423. The predicted detection rate is given by:

$$\frac{dN_{\text{Swift}}}{dz} = f_{\text{Swift}} \epsilon_{\text{SED}} \epsilon_{\text{beam}} \frac{dN}{dz} \text{ yr}^{-1},$$

where $N$ is the intrinsic rate of GRBs (see § 5.2), $\epsilon_{\text{beam}}$ is a correction factor for GRB beaming (see § 6.1), $\epsilon_{\text{SED}}$ is the fraction of GRBs above the Swift detection threshold (see Fig. 6 and § 6.1), and $f_{\text{Swift}} = 1.4/(4\pi) = 0.1$ represents the Swift sky coverage (Gehrels et al. 2004; Barthelmy et al. 2005). We plot our prediction for the observed rate of both short and long GRBs in Swift in Figure 7. In the redshift range $z = 6.2-7.2$ centered on $z = 6.7$ (GRB 080913), we expect Swift GRB detection rates of:

$$N_{\text{Swift, long}} \sim 0.33-5.0 \text{ yr}^{-1} \text{ at } z = 6.2-7.2$$  \hspace{1cm} (22)

$$N_{\text{Swift, short}} \sim 0.01-0.70 \text{ yr}^{-1} \text{ at } z = 6.2-7.2.$$  \hspace{1cm} (23)

For the redshift range $z = 7.6-8.6$ centered on $z = 8.1$ (GRB 090423), the predicted Swift detection rates become:

$$N_{\text{Swift, long}} \sim 0.21-2.2 \text{ yr}^{-1} \text{ at } z = 7.6-8.6$$  \hspace{1cm} (24)

$$N_{\text{Swift, short}} \sim 0.004-0.24 \text{ yr}^{-1} \text{ at } z = 7.6-8.6.$$  \hspace{1cm} (25)

These results suggest that GRB 080913 and GRB 090423 are most likely associated with the deaths of massive stars (long GRBs), rather than double compact object mergers (short GRBs). At redshifts $z = 6.7$ (GRB 080913) and $z = 8.1$ (GRB 090423) long GRBs are expected to be $\sim 10$ times more frequent than short GRBs in the Swift sample. We emphasize that we have taken an optimistic value for the short burst observational threshold; the true short GRB rate may be up to an order of magnitude smaller (see § 6.1 for details). Our results thus represent an upper-limit to the short GRB fraction at these high redshifts. Although the intrinsic event rates for collapsars and double compact object mergers are similar at these high redshifts, the observational difference is due to the very distinct observational selection effects between these two event types. We note that our results are consistent with Zhang et al. (2009), who classified both bursts as collapsars based upon their observational properties. We have ignored recent evidence that the long GRB population evolves with redshift, increasing the number of observed bursts at high redshift. In this sense, our results can be considered a lower limit to the long GRB rate (although we note that the corresponding evolution of short bursts is currently poorly constrained). Further details of the nature of GRB intrinsic properties and observational selection effects can be found for example in Guetta, Piran & Waxman 2005; Guetta & Piran 2006; Berger 2007; Kistler et al. 2008; Salvaterra et al. 2009 and Virgili, Liang & Zhang 2009.

---

1Our fluence threshold can easily be rephrased as a trigger on peak flux/luminosity, with all of the units being converted from [erg] to [erg s$^{-1}$]. The results are identical. In addition, we are calculating the fluence from an isotropic luminosity, but the results are unchanged if this is taken to be a beamed luminosity.
We have calculated the evolution of stars at high redshift, exploring possible progenitors for GRB 080913 (at $z = 6.7$) and GRB 090423 (at $z = 8.1$). We find that in the redshift range $6 \lesssim z \lesssim 10$ the majority of stars are Population II (low metallicity). By this time Population III stars (metal free) have already finished their evolution, and Population I stars (metal rich) are only just beginning to form. We have adopted two extreme models for the metallicity evolution history, which most likely bracket the true history; our final results are insensitive to the choice of model. We find that the progenitors of GRB 080913 and GRB 090423 are likely to have been Population II stars.

For Population II stars we subsequently calculated the rates of double compact object mergers (NS-NS and BH-BH) and the rates of collapsars (deaths of massive stars). The former are thought to be associated with short GRBs, while the latter are believed to be responsible for long GRBs. We find that the intrinsic rates for short GRBs (mergers) and long GRBs (collapsars) are comparable at GRBs. We find that the intrinsic rates for short GRBs are most likely to have been long bursts, resulting from the deaths of massive stars (collapsars) from Population II progenitors. With the observation of GRB 080913 and 090423, gamma-ray bursts have entered a unique high-redshift regime. As future data fills out the high-$z$ tail of GRBs, these systems will become one of the most powerful probes of the star formation, stellar death, and chemical enrichment of our Universe.

We thank the anonymous referee for encouraging us to incorporate observational selection effects into our analysis. KB acknowledges support from KBN grant N N203 302835.

Fig. 1.— Bottom panel: Star formation rate history. We have adopted an extinction corrected SFR model from Strolger et al. (2004): all stars. We also show the rate we have obtained for just Population II stars (see §2): the population is rather different for slow (solid) and fast (dashed line) metallicity evolution model. Top panel: Metallicity distribution of stars at redshift $z = 7.0$. The results are shown for the two different adopted metallicity evolution histories: fast (Young & Fryer 2007) and slow (Pei et al. 1999). We mark our definition for Population II stars: it is clearly seen that independent of metallicity evolution majority of the stars belong to Population II at redshift that is typical for stars that may become (after appropriate delay) progenitors of GRB 080913.
Fig. 2.— Top panel: Delay times for long GRB progenitors: direct black holes that are formed out of H-depleted stars (both single and binary). Note the very short delay times of \( \lesssim 6 \) Myr. Delay is evolutionary time a star takes from the formation to a collapse. Bottom panel: Delay times for short GRB progenitors: NS-NS and BH-NS mergers. Note that these events have significantly longer delay times than for the long GRB progenitors, with a median of 0.1 Gyr. Delay time is evolutionary time plus merger time.
Fig. 3.— Short and long GRB \textit{intrinsic} event rate densities (in the restframe) originating from Population II stars for slow and fast metallicity evolution. These are expressed per year, per cubic comoving Gpc.
Fig. 4.— Intrinsic event rate of short and long GRBs that originate from Population II stars, per year (in the observer frame), as a function of the depth of the survey in redshift, $z$. The rates are shown for slow and fast metallicity evolution models.
Fig. 5.— *Intrinsic* event rate of short and long GRBs that originate from Population II stars, per year (in the observer frame) presented per unit redshift. These plots show the derivative of curves presented in Figure 4 highlighting the redshift range in which GRB events from Population II stars contribute.
Fig. 6.— **Top panel:** Distribution of total energy ($\mathcal{E} = L_{\text{iso}}t_{90}$) for short and long GRBs. Short and long GRBs are assumed to have the same distribution of average isotropic luminosity, $L_{\text{iso}}$, described by a Gaussian in log($L_{\text{iso}}$) with mean at log($L_{\text{iso}}/[\text{erg s}^{-1}]$) = 50 and $\sigma$ = 1.0. A single typical duration time was assumed for all short ($t_{90} = 0.3s$) and long ($t_{90} = 30s$) GRBs. The adopted *Swift* detection thresholds (at $z = 1.0$) are also shown; $\mathcal{E} = 10^{50}$, $3 \times 10^{50}\text{erg}$ for short and long GRBs, respectively. See the text for details. **Bottom panel:** The fraction of GRBs above the *Swift* detection limit, $\epsilon_{\text{SED}}$, as a function of redshift. Note that at redshift $z = 6.7$ (GRB 080913) the fraction of detectable long GRBs is $\epsilon_{\text{SED,long}} = 0.162$, while for short events it is only $\epsilon_{\text{SED,short}} = 0.006$. At redshift $z = 8.1$ (GRB 090423) the difference in detection probability is even larger: $\epsilon_{\text{SED,long}} = 0.118$ and $\epsilon_{\text{SED,short}} = 0.004$. 
Fig. 7.— Predicted *Swift* detection rates of short (NS-NS/BH-NS mergers) and long (collapsars) GRBs. Rates are for GRBs originating *exclusively* from Population II stars, and hence can only be compared to *Swift* data in the redshift range in which Population II stars are the dominant stellar population: $6 \lesssim z \lesssim 10$ (as marked on the plot). For low redshifts ($z \lesssim 6$) there is a significant contribution to GRB rates from Population I stars (not shown here), and for very high redshifts ($z \gtrsim 10$) there may be a contribution from GRBs originating from Population III stars (not shown here). Note that GRB 080913 and GRB 090423 are both found in the redshift range in which the majority of GRB events are predicted to originate from Population II stars. Furthermore, our results favor the collapsar origin for these GRBs. The two panels show the rates for a fast (early metal mixing into stars; top panel) and a slow (late mixing; bottom panel) metallicity evolution model. In the redshift range of interest ($6 \lesssim z \lesssim 10$), the rates of the two extreme models are similar, indicating that our conclusions are robust: GRB 080913 and GRB 090423 have Population II progenitors, and are both long bursts resulting from collapsars.
