Abstract. Pancreatic cancer (PC) is a highly malignant tumor type with a high early metastasis rate and no obvious symptoms. Gemcitabine is a first-line chemotherapeutic drug for PC. Since there is no distinct method to determine the efficacy of chemotherapy with gemcitabine in patients with PC, the purpose of the present study was to determine whether positivity for circulating tumor cells (CTCs) in patients with advanced PC is associated with response to gemcitabine chemotherapy and to explore whether CTCs may be used as a predictor of prognosis of patients with advanced PC undergoing chemotherapy. First, immunomagnetic microspheres (magnetic beads; MIL) were prepared to detect CTCs. The patients' clinical characteristics and survival data, as well as efficacy and adverse effects of chemotherapy, were prospectively obtained and their association with CTCs was analyzed. The results indicated that CTC-positive patients with advanced PC had a higher probability of developing resistance to gemcitabine chemotherapy than CTC-negative patients. Survival in the CTC-negative group was significantly higher than in the CTC-positive group ($\chi^2=14.58$, $P<0.001$). CTC-positive patients with advanced PC also had shorter progression-free survival (PFS) after chemotherapy with gemcitabine ($P=0.01$). In conclusion, CTC-positive patients with PC are more likely to develop gemcitabine resistance, have poor PFS and low incidence of thrombocytopenia. CTCs are expected to become a prognostic indicator for chemotherapy response in patients with PC.

Introduction

Pancreatic cancer (PC) is a digestive system malignancy and the most common pathologic type is pancreatic ductal adenocarcinoma (PDAC). In 2018, an estimated 458,918 patients were newly diagnosed with PDAC worldwide, accounting for ~2.5% of the total new cases in all cancer types, and ~432,242 PDAC-associated mortalities occurred, accounting for ~4.5% of the total cancer-associated deaths (1,2). Furthermore, PC is often diagnosed at an advanced stage and the only treatment available is palliative care, such as chemotherapy and radiotherapy (3). PC is not sensitive to palliative treatment during the late stage in the majority of cases (3). Complete surgical resection is the only effective method for the treatment of PDAC (4). However, only 15-20% of patients with PDAC may have the opportunity to undergo curative surgical tumor resection, while the remaining patients can only receive adjuvant therapies. In this case, adjuvant therapies refer to chemotherapy or radiation therapy alone, as extensive metastasis and advanced tumor stage means surgery is no longer an option (5).

Gemcitabine is a first-line chemotherapy drug approved by the Food and Drug Administration for PDAC (6,7). The development of gemcitabine resistance during chemotherapy affects the prognosis of advanced PDAC and has become an increasingly common phenomenon (8). Although PDAC is not sensitive to chemotherapy, gemcitabine may still alleviate the symptoms of patients with PDAC and prolong their survival time (9). However, it has been reported that PDAC is gradually becoming resistant to gemcitabine and its efficacy declines (10,11). As patients with advanced PDAC cannot be treated with surgery, they may only be treated with gemcitabine chemotherapy; however, a considerable number of patients develop resistance. Therefore, it is important to predict whether patients will develop gemcitabine resistance through certain methods.

Circulating tumor cells (CTCs) may be used as a predictor of advanced metastasis of malignant tumors (12). Previous studies have indicated that the amount of CTCs in the blood may predict the prognosis of breast cancer and PC (13-15). PC subtypes with CTCs are more aggressive and metastatic (16,17). In addition, an increase in the number of CTCs in the portal vein blood may reduce the survival of patients with PDAC (18,19). CTCs have been determined to be an
independent prognostic factor of PDAC; however, the relationship between CTCs and gemcitabine resistance has been rarely studied (20). In the present study, it was hypothesized that CTCs may be used as an independent prognostic factor for patients with PDAC and to be related to gemcitabine resistance in patients with advanced PC. The immunomagnetic microsphere used for sorting CTC in this study were EpCAM (12). The purpose of the present study was to test the above hypothesis by detecting changes in CTCs during PDAC treatment.

Materials and methods

Patients and clinical samples. The clinicopathological factors and blood samples in the present study were obtained from 87 patients with advanced PDAC who underwent chemotherapy with gemcitabine between June 2013 and June 2017 at the Second Affiliated Hospital of Jiaxing University (Jiaxing, China). The patient inclusion criteria were as follows: i) Accurate pathological diagnosis of primary PDAC; ii) complete clinicopathological and follow-up data; iii) lack of opportunity of surgery and tumor-node-metastasis (TNM) stage of III or IV. The patient exclusion criteria were as follows: i) The patient had undergone surgery and chemotherapy prior to admission; ii) the diagnosis was not clear; iii) presence of more than two primary tumors.

All patients were tested with serum tumor markers prior to chemotherapy, such as carcinoembryonic antigen (CEA) and carbohydrate antigen 199 (CA199). Patients were classified and staged based on the TNM classification for PDAC established by the Union for International Cancer Control (21). The clinicopathological data are provided in Table I. The present study was approved by the Ethics Committee of the Second Affiliated Hospital of Jiaxing University. Informed consent was obtained from each participant. All patients had advanced PC and no chance of surgery. Endoscopic ultrasound-guided fine-needle aspiration was used for pathological examination and 5 patients had squamous cell carcinoma. CT and MRI were used to examine vascular invasion.

Chemotherapy and clinical evaluation. All 87 patients were treated with gemcitabine as a first-line chemotherapy drug. Each patient was treated with gemcitabine 1,000 mg/m² administered as an intravenous drip for 30 min. This medication was given on the 1st, 8th and 15th days of the course of treatment with a rest period for 14 days and every course of treatment lasted 28 days. This was repeated until progression or adverse reactions of chemotherapy became intolerable. All 87 patients received chemotherapy for >8 weeks. As the evaluation standard for adverse reactions, the grading standard (CTCAE3.0) established by the National Cancer Center of the United States was used (22). Progression-free survival (PFS) was defined as the time from the date of the diagnosis to the date of progression or death. Overall survival (OS) was defined as the time from the date of the diagnosis to the date of death or the last follow-up examination.

Preparation of immunomagnetic microspheres. To perform modification of epithelial cell adhesion molecule (EpCAM) by glycylidhexadeclamide (GHDC), 57.1 µg of EpCAM (cat. no. ab223582; Abcam), dissolved 100 µg of GHDC (cat. no. 30-CG-049; Huzhou Liyuan Medical Laboratory Co., Ltd.) and 3.0 ml PBS (pH 7.4) was reacted with magnetic stirring at 4°C overnight. The molecules to be retained in the dialysis bag with a molecular weight of 8,000-14,000 Da were used the next day for 12 h and the buffer (PBS) was changed every 2 h. The antibody derivative EpCAM-GHDC obtained by dialysis and lyophilization was weighed. GHDC, immunomagnetic microspheres and dialysis bags were purchased from Huzhou Liyuan Medical Laboratory Co., Ltd. The preparation procedure of EpCAM immunomagnetic microspheres is displayed in Fig. 1A. During the preparation of immunomagnetic microspheres, GHDC was able to interact with transferrin antibodies. Hexadeyl-quaternized (carboxymethyl) chitosans (cat. no. 30-CG-050; Huzhou Liyuan Medical Laboratory Co., Ltd.) increased the grafting quantities of magnetic microspheres and antibodies through reactive groups and exerted emulsification, dispersion and surface activation functions (23,24).

Characterization of EpCAM magnetic spheres. The size distribution and zeta potential of the EpCAM magnetic spheres were measured by a Zetasizer (Nano-ZS 90; Malvern Instruments, Ltd.). The molecular morphology of folic acid magnetic spheres was determined via atomic force microscopy (BioScope SPM; Bruker Corporation). The magnetic properties of EpCAM magnetic spheres were measured via a vibrating sample magnetometer (Model 7407; Lake Shore Cryotronics, Inc.) and the ultraviolet absorption spectrum of EpCAM magnetic spheres was measured using a UV-2501PC UV-Vis spectrophotometer (Shimadzu Corporation).

CTC detection. The CTC detection procedure for PC is displayed in Fig. 1B. EpCAM immunomagnetic microspheres, prepared according to Fig. 1A, were added to the peripheral blood of patients with PDAC and the captured CTCs were identified and counted by immunofluorescence. Peripheral blood (4 ml) from 87 patients with advanced PDAC was collected in anticoagulation tubes prior to any treatment, and subsequently, 14 ml of red blood cell lysate from the same patient was added within 2 h. The sample was mixed gently by pipetting, placed in a refrigerator at 4°C for 15 min and then centrifuged at 111 x g for 5 min at 4°C. The supernatant was discarded and to the cell pellet, 10 ml buffer [PBS 500 ml + EDTA 0.375 g + BSA (Thermo Fisher Scientific, Inc.) 2.5 g] was added using the Nextctc FS100 Nano microfluidic chip (Wuxi Nao Biomedical Co., Ltd.). Obtained CTCs were evenly poured onto the slide. Sections were fixed with 2% paraformaldehyde for 10 min at room temperature and 0.25% Triton X-100 for 10 min. Subsequently, sections were washed with PBS for 15 min (three times for 5 min), and incubated with 2% BSA for 30 min at room temperature to block nonspecific binding. The sample was then incubated for 20 min at room temperature with EpCAM antibody (1:200 dilution; cat. no. ab223582; Abcam), cytokeratin (CK)-18 antibody (1:200 dilution; cat. no. ab181597; Abcam) or CD45 antibody (1:200 dilution; cat. no. SAB4502541; Sigma-Aldrich; Merck KGaA). Subsequently, the samples were rinsed with PBS for 15 min (3 times for 5 min). The sections were incubated
Table I. Characteristics of patients with advanced pancreatic cancer (n=87).

| Parameter                        | Value     |
|----------------------------------|-----------|
| Age, years                       | 61.8 (45‑86) |
| Sex (male/female)                | 50/37     |
| Pathological type (adenocarcinoma/squamous cell carcinoma) | 79/8 |
| Serum CA199, U/l (positive/negative) | 52/35 |
| Serum CEA, U/l (positive/negative) | 24/53 |
| TNM stage (III/IV)               | 40/47     |
| Tumor location (head and neck/tail) | 65/22 |
| Tumor size, cm                   | 3.9 (2‑7) |

Values are expressed as the mean (range) or n. CEA, carcinoembryonic antigen; CA199, carbohydrate antigen.

with DyLight 488-conjugated donkey anti-mouse IgG (H+L) (1:200 dilution; cat. no. ab150105; Abcam) and anti-rabbit IgG (1:200 dilution; cat. no. ab150073; Abcam) for 2 h at room temperature. Subsequently, the sections were washed with PBS for 15 min, mounted with mounting medium and examined under a fluorescence microscope (Olympus BX51; Olympus Corporation). CTCs were characterized by lacking CD45 expression and expressing EpCAM. CK immunocyto‑fluorescence staining was also assessed on detected CTCs.

Detection results of CTCs and efficacy of chemotherapy. The present study included 87 patients with PDAC treated between June 2013 and June 2017. As indicated in Table I, the age ranged between 45 and 86 years (mean age, 61.8 years), the cohort contained 50 males and 37 females, 22 tumors were located in the tail of the pancreas and 65 cases were located in the head and neck of the pancreas. Among them, 49 patients (56%, 49/87) had one or more CTCs/4 ml blood detected, with CTC numbers ranging from 2 to 298 (mean ± standard deviation, 109.2±71.6) (Fig. 3A). The Kaplan‑Meier plots for PFS and OS for patients with PC were drawn and it was indicated that CTC positivity was associated with poor PFS compared with CTC negativity (P<0.01). However, the OS rate of CTC-positive patients was not significantly different from that of CTC-negative patients (P=0.091; Fig. 3B and C).

Results

Characterization and performance evaluation of immunomagnetic microspheres. In order to examine the performance of the constructed CTC capture system, a series of functional tests were used to analyze the characteristics of the magnetic beads constructed. The UV spectrum proved that the EpCAM antibody had a broad absorption peak at 278 nm (Fig. 2A). For EpCAM-magnetic beads (MIL), an absorption peak was present at 281 nm. This indicated that EpCAM was indeed attached to the surface of the magnetic spheres. The UV spectrum of EpCAM-MIL had diffraction peaks at 31.5, 36.7, 42.9, 53.2, 58.2 and 61.5°, respectively, which corresponded to the (219), (312), (401), (420), (509) and (439) crystal plane structures of Fe3O4, respectively (Fig. 2B). The above results indicated that the magnetic beads were composed of Fe3O4 and that EpCAM was successfully attached to the surface of the magnetic beads. The immunomagnetic beads exhibited the crystal characteristics of magnetic nanoparticles. The magnetization curve indicated that the Fe3O4-MIL and EpCAM-MIL had no hysteresis at room temperature, but were super-paramagnetic, and the magnetizing curve was displayed at 302 Kelvin. In addition, these results also proved that the saturation magnetization of the MIL was 27.75 Am2/kg and the synthetic saturated magnetization of EpCAM-MIL was 10.03 Am2/kg, indicating the saturation magnetization of the magnetic beads on the surface of the antibody and protein coating was immunomagnetic (Fig. 2C). The atomic force microscopy image of EpCAM-MIL illustrated that the size of the EpCAM-MIL was spherical and no agglomeration was present, which indicated that the microspheres had good stability and shape (Fig. 2D). As presented in Fig. 2E, the particle size test results of EpCAM-MIL suggested that the size of the spheres was ~400 nm and the average particle size was 323.9 nm, which indicated liposome-like vesicle properties. At the same time, the zeta potential analysis results of EpCAM-MIL suggested that the zeta potential was +23.9 mV (Fig. 2F). In summary, the magnetic beads prepared in the present study have smaller particle size and higher stability than those described in a in previous study (25).

Relationship between CTCs and clinicopathological characteristics of patients with advanced PC. The relationship between CTCs and the clinicopathological characteristics of 87 patients with advanced PDAC was analyzed by the χ2 test.
Univariate analyses demonstrated that CTCs were closely associated with vascular invasion (P<0.001), TNM stage (P=0.005) and liver metastasis (P=0.005). However, there was no significant difference between CTCs and other clinical parameters, including age, sex, symptoms, tumor size, tumor location, pathological type, lymph node metastasis, neurological invasion, CA199 and CEA. Multivariate regression analysis indicated that vascular invasion (P<0.001) and liver metastasis (P=0.002) were independent predictors of CTCs.

Relationship between chemotherapy effect and CTCs. According to the analysis, 77.5% of the CTC-positive patients were resistant to gemcitabine, while 47.4% of CTC-negative patients developed resistance to gemcitabine. The detailed data for the association between peripheral blood CTC and chemotherapeutic efficacy of gemcitabine are displayed in Fig. 4, which indicated that the efficacy of gemcitabine was also affected by CTCs ($\chi^2=8.501, P=0.004$). The sensitivity and specificity of CTC detection for gemcitabine resistance was calculated as follows: Sensitivity, 67.86% and
specificity, 64.52%. However, there was no significant association between the chemotherapy effect and other clinical parameters, including age, sex, symptoms, tumor size, tumor location, CA-199, CEA, liver metastasis and TNM stage (Table III).

Relationship between chemotherapy adverse reactions and CTCs. All 87 patients with advanced PDAC were able to tolerate adverse reactions to gemcitabine chemotherapy and no chemotherapy-related death occurred. The major adverse reactions were digestive tract reactions, myelosuppression
and flu-like symptoms. The incidence of thrombocytopenia in the CTC-negative and -positive groups was 57.8 and 18.4%, respectively, and that in the CTC-negative group was significantly higher than that in the-positive group ($\chi^2=14.58$, $P<0.001$), but other adverse reactions, including digestive tract reactions, myelosuppression, anemia, liver damage and flu-like symptoms were not associated with CTCs (Table IV).

**Discussion**

In the present study, it was confirmed that patients with advanced PDAC have poor prognosis and short survival. Furthermore, CTC-positive patients with advanced PDAC had a higher ratio of resistance to gemcitabine and lower efficacy of chemotherapy. The use of CTC count statistics and related research is of great significance for the dynamic monitoring of PDAC clinical samples (26,27).

PDAC is the fourth leading cause of death worldwide. The lack of early symptoms and screening usually results in late diagnosis and poor prognosis. CTCs have been a promising novel biomarker in solid tumors. Over the past two decades, >100 articles have been published on this topic. Most of the studies evaluated the use of CTCs as a prognostic marker and its association with the survival of patients with PDAC (28). Patients with advanced PDAC may exhibit multiple complications associated with distant metastasis (29,30). The present study indicated that the positive rate of peripheral blood CTCs in 87 patients with advanced PDAC was 56%. Han et al (17) combined nine articles in a meta-analysis, revealing a CTC-positive rate of 43% in 623 patients with PDAC. The meta-analysis suggested that CTC-positive patients with pancreatic cancer exhibited worse levels of PFS and OS, compared with CTC-negative patients (17). Of note, the CTC data of patients with metastatic PDAC using the CellSearch® system indicated that the detection rate of CTCs is ~50% (18-20). The higher CTC-positive rate in the present study was likely due to the patients having advanced PDAC and the limited sample size. This still indicated that the self-assembled lipid beads used had a good CTC capture ratio.

Pancreatic adenocarcinoma has a moderate response to gemcitabine-based chemotherapy, which is the most widely used monotherapy for PDAC. Tadros et al (31) discovered a marked increase in gemcitabine resistance in patients with pancreatic cancer following the orlistat-induced inhibition of fatty acid biosynthesis. Using the Cancer Genome Atlas dataset, Tadros et al indicated that fatty acid biosynthetic pathway manipulation may help overcome the stress and regulation of gemcitabine in PDAC (31). Furthermore, Shukla et al (32) declared that targeting HIF-1 cells or de novo pyrimidine biosynthesis, combined with gemcitabine, may significantly
reduce the tumor burden and decrease the expression of transketolase and cytidine triphosphate synthase 1. In addition, Mehla and Singh (33) revealed that a glycolytic subtype indicates poor survival in patients with PDAC, whereas the holesterogenic subtype correlates with more favorable outcomes, potentially due to a higher energy expenditure. The detection of CTCs may be of important clinical value for the prognosis of PC. The purpose of the present study

Hypothesis testing was carried out on the whole model, that is, testing whether the relationship between the dependent variable and the independent variable can be expressed by the established regression equation. It has been tested whether the single regression coefficient is 0, that is, whether the influence of a single independent variable on the dependent variable exists. The variables with statistically significant differences in univariate analysis were taken as independent variables and included in the Logistic regression model. The stepwise forward regression method was adopted for analysis. The inclusion standard was 0.05 and the exclusion standard was 0.1. *Fisher's exact test. Values are expressed as the mean ± standard deviation, median (range) or n. CTC, circulating tumor cell; CEA, carcinoembryonic antigen; CA199, carbohydrate antigen 199; OR, odds ratio.
was to evaluate the role of CTCs in recurrence, metastasis and treatment efficacy by detecting the differences in CTCs between patients with PDAC. Most previous studies have explored the association between CTC detection and PC
diagnosis. Both Earl et al (34) and Liu et al (35) reported that CTCs are a promising marker for the management of patients with PDAC; however, the correlation between CTCs and gemcitabine resistance in patients with PDAC has remained largely elusive. The present study not only confirmed that CTCs are a prognostic marker in patients with advanced PC undergoing chemotherapy, but also that CTC-positive patients with PC are more likely to develop gemcitabine resistance. In the present study, all 87 patients with advanced PDAC received gemcitabine monotherapy. Among them, 56 patients were resistant to gemcitabine and the drug resistance rate was 64%. The resistance rate of gemcitabine in CTC-positive patients with PDAC was as high as 77.6% (28/39). Previous studies have indicated that the resistance rate of patients with PDAC to gemcitabine is gradually increasing, and the efficacy of gemcitabine is also reduced by >20%, compared to the results established ~10 years prior (5,6). The present clinical study confirmed that positivity for CTCs prior to chemotherapy in patients with PC indicates drug resistance, but the mechanisms have remained elusive. Based on the combination of results of previous studies, it may be hypothesized that epithelial to mesenchymal transition (EMT) may be associated with changes in CTCs and gemcitabine resistance (16,36). This is a process associated with the separation of cancer cells from the primary tumor, which may lead to CTCs that metastasize, contributing to cancer progression. Thus, the number of CTCs can be used as an indicator for cancer progression and its degree of malignancy. The further the cancer has progressed, the worse the prognosis, and the poorer the efficacy of gemcitabine. Although the expression of EpCAM was detected and the relevant literature was reviewed, it was determined that the mechanism of action underlying CTCs in pancreatic cancer may be associated with EMT. In the present study, the method used was not able to detect the expression of E-cadherin and vimentin due to the use of peripheral blood primary cells of patients for CTC detection. Furthermore, peripheral blood samples cannot easily be stored for long periods of time, thus, relevant substances in the blood are lost over time. This is also the difficulty of CTC detection at present. Previous methods have also failed to do this, for example, Xie et al (37) used an in vivo CellCollector® method to detect the number of CTC in patients. In the future, more convenient and sensitive testing methods will be applied (37). Previous studies have indicated that gemcitabine combined with nab-paclitaxel chemotherapy may optimize the chemotherapy effect of PDAC and prolong the survival time (38,39). Therefore, improving the sensitivity of PDAC cells to gemcitabine and combined chemotherapy may improve the chemotherapy effect and prolong the survival time of patients. In the present study, the median PFS was 8.0 months in CTC-positive patients compared to 7.0 months in CTC-negative patients. However, OS did not differ significantly between CTC-positive and CTC-negative patients with PDAC. In general, the median survival time of PDAC is low, but a minority of patients with PDAC have undergone complete surgical resection, so their survival time is particularly long (40). In those patients eligible for surgery, the cancer was at an early stage without metastasis, and the associated prognosis was improved. Furthermore, the present study determined that patients with advanced PDAC with CTCs were less likely to develop thrombocytopenia after receiving gemcitabine, but the reason for this remains elusive.

The present study has certain limitations that are worth mentioning. Due to the limited number of patients included, the results of related studies should also be considered. The present study is a retrospective study and the results obtained require to be verified by larger prospective studies. In addition, the patients of the present study were not monitored for CTCs after treatment due to cost considerations. In subsequent studies, a comparative study evaluating CTCs prior to and after treatment may be performed.

In conclusion, CTC-positive patients with PC are more likely to develop gemcitabine resistance, and these patients have poor PFS and low incidence of thrombocytopenia. Thus, CTCs may be considered as a prognostic marker for chemotherapy in patients with advanced PC.

Funding

The present study was supported by the Medical and Health Science & Technology Planning Project of Zhejiang Province (grant no. 2019KY219) and the Science and Technology Planning Project of Jiaxing City (grant no. 2018AY32003).

Availability of data and materials

The datasets used and/or analyzed during the current study are available from the corresponding author upon reasonable request.

Authors’ contributions

ZZ was responsible for project design, obtaining funding and resources, and conceptualization. XW was also responsible for project conceptualization. FC was also responsible for obtaining resources. XW, LH and XY were responsible for drafting the manuscript. LH conceived and designed the CTC extraction experiment, analyzed the experimental data, wrote the results and discussion in the manuscript, and generated Figures 1 and 3, and Table II. In addition, LH made a significant contribution to manuscript revision. XY made substantial contributions to acquisition of data. LH was responsible for data curation, statistical analysis and experimentation. HY was responsible for carrying out the experiments. HX, FC and JF were responsible for performing the experiments. ZZ made substantial contributions to analysis and interpretation of data, and producing figures and tables of analysis results. All authors confirm the authenticity of the raw data. All authors read and approved the final manuscript.

Ethics approval and consent to participate

This study was approved by the Ethics Committee of the Second Affiliated Hospital of Jiaxing University (Jiaxing, China). Informed consent was obtained from each study participant.
Patient consent for publication

Not applicable.
