ABSTRACT

Aim: Tryptophan hydroxylase-2 mRNA (TPH, the rate limiting enzyme in 5-HT synthesis) expression levels display circadian variations in the median and dorsal raphe nuclei. This circadian pattern is under the control of the suprachiasmatic nuclei (SCN), the master clock. Photoperiodic cue is encoded by the SCN which convey the seasonal message to target sites. In the present study, we have investigated the effect of photoperiodic changes on the serotonergic neurons of the raphe nuclei. We have assessed the daily expression of TPH2 mRNA in both median and dorsal raphe nuclei of rats housed either under long photoperiod (18 h light/6 h dark cycle, LP18:6) or short photoperiod (SP6:18).

Results: Our results demonstrate that under LP18:6, TPH2 mRNA levels display a progressive decrease during the dark period and a maximal expression is reported at the beginning of the light period. The expression pattern of TPH2 mRNA under SP6:18 remains unchanged during the dark period and increases significantly before the light/dark transition. This latter expression pattern is in line with the daily profiles of TPH2 mRNA reported previously under standard lighting regimen (12 h light/12 h dark cycle).

Conclusion: The present results suggest that TPH2 mRNA expression pattern within DR and MR is affected by photoperiod which might in turn affect TPH content and 5-HT release within the circadian structures, but also in all the serotonergic projection areas of the brain.

INTRODUCTION

Serotonin (5-HT) plays an important role in both photic and non-photic resetting of the central circadian pacemaker residing in the suprachiasmatic nuclei (SCN) of the hypothalamus [1, 2]. A direct serotonergic afferent pathway to the SCN arises from the median raphe (MR) nucleus, whereas the dorsal raphe (DR) nucleus projects indirectly to the SCN through the thalamic intergeniculate leaflets (IGL) [3, 4]. Both tryptophan hydroxylase (TPH, the rate limiting enzyme in 5-HT synthesis) content and 5-HT release display circadian variations within the serotonergic fibres in the SCN of rat [5]. Furthermore, TPH protein and TPH2 mRNA (encoded by the neuronal tph gene: tph2) levels undergo circadian variations in both DR and MR [6, 7]. The circadian pattern of TPH2 mRNA expression has been shown to be directly controlled by corticosterone daily surge, a neuroendocrine output of the clock [8].

While several features of serotonergic neurons have been characterized, the impact of photoperiod (the annual change in the day length) on the general functioning of these neurons is poorly investigated. Indeed, little is known about the photoperiodic-related changes in the synthesis and the release of 5-HT within the time-keeping system. For instance, the rhythmic release of 5-HT in the SCN and the IGL of Syrian and Siberian hamsters was only investigated under long photoperiod [9–11]. On the other hand, among the studies performed on rats, the intra-SCN 5-HT release was only examined under 12 h light:12 h dark cycle (LD12:12) [5]. Furthermore, to our best knowledge, the photoperiodic regulation of the daily pattern of TPH protein and TPH2 mRNA has never been studied.

Annual changes in photoperiod lengths are often associated with mood disorders such as depression and bipolar disorder, in which drastic changes in serotonergic neurotransmission system in the brain were reported. The duration of daylight, the photoperiod, will certainly impact the functional characteristics of the Raphe neurons especially Serotonin synthesis.

The photoperiodic information is encoded by the SCN clock which displays photoperiod-related changes...
in its electrical activity [12, 13] and genes expression [14–16]. The circadian pacemaker distributes the photoperiodic message to the target sites via several endocrine outputs. Melatonin secretion is one of these outputs and is considered as an internal message that ensures seasonal timing [17–19]. In addition, daily secretion of corticosterone is affected by the day-length in rats housed under short and long photoperiod and could therefore carry photoperiodic changes to glucocorticoids sensitive neurons [20–22].

The aim of this study was to investigate whether the photoperiodic environment could influence the functioning of the serotonergic neurons in the DR and the MR. Thus, we have assessed the daily expression of TPH2 mRNA in both raphe nuclei of rats housed either under long or short photoperiod.

**Materiel and methods**

**Animals**

All experiments were performed in accordance with NIH Guidelines regarding the care of laboratory animals, with the European Communities Council Directive of 24 November 1986 (86/6.9/EEC) and the French laws.

Adult male Wistar rats weighing 180–200 g were purchased from the faculty of medicine in Strasbourg (France) and kept in animal’s facilities for a period of 1 week for acclimation. Animals were then divided into two groups: the first group was placed under long photoperiod which corresponds to 18 h light and 6 h dark cycle (LP6:18, lights on from 05h00 until 23h00). The second group was transferred into short photoperiod (SP6:18, lights on from 14h00 until 20h00). Animals had free access to food and water during the period of this experiment. Rats in both groups were kept 4 weeks under LP or SP conditions and then killed by decapitation at seven time-points across the light/dark cycle. Four animals were killed at each of the following time points: 24h00, 02h00, 04h00, 09h00, 13h00, 17h00 and 21h00 for the LP group and 21h00, 23h00, 02h00, 06h00, 10h00, 13h00 and 18h00 for the SP group. Brains were quickly removed, frozen in cold isopentane and stored at −80°C until tissue preparation. Trunk blood was collected into heparinized tubes and centrifuged (2800 rpm at 4°C) and the resulting plasma was used for melatonin radioimmunoassay in order to confirm the integration of the photoperiodic change.

**In situ hybridization procedure**

Brains were cut in serial coronal sections (20 µm thick) with a cryostat (Leica Instruments GmbH, Nussloch, Germany) throughout the rostral part of the Raphe, including DR and MR (Interaural from +1.9 mm to +0.7 mm, according to the Paxinos and Watson atlas) and collected on gelatine-coated slides.

For *in situ* hybridization, sense and antisense riboprobes for TPH2 were prepared as described previously [7, 8], by using the corresponding linearized plasmids and the appropriate polymerase (MAXI script, Ambion, USA) in presence of [35S]-UTP (1250 Ci/mmol, Amersham, UK).

Hybridization was performed as following: sections were postfixed in 4% formaldehyde and then acetylated twice in triethanolamine (0.1 M, pH 8.0) with 0.5% acetic anhydride. Thereafter, sections were rinsed, dehydrated in graded ethanol and air-dried. Hybridization was carried out at 54°C overnight in humid boxes by depositing 100 µl of TPH2 riboprobes (300 pM). The hybridization solution contained 50% deionised formamide, 2X sodium saline citrate (SSC), 1X Denhardt’s solution, 0.25 mg/ml yeast tRNA, 1 mg/ml salmon sperm DNA, 10% dextran sulphate and 10 mM dithiothreitol. After hybridization, the sections were treated with Ribonuclease A at 37°C (1.4 µg/ml, Sigma, USA). Stringency washes were then performed in 4X SSC, 2X SSC, 0.5X SSC and 0.2 X SSC. Finally, sections were dehydrated in graded ethanol, air-dried, and exposed for 24 h to an autoradiographic film (Kodak BioMax).

**Melatonin radioimmunoassay**

Melatonin was extracted from plasma samples using dichloromethane and assessed in duplicates using a specific rabbit antiserum at 1:90,000 (R 19540, INRA, Nouzilly, France) and [125I]-2-iodomelatonin. Melatonin assay detected values as low as 5 pg/ml, and the reproducibility of the method was determined by evaluating the INTRA-assay variation (2.5%) and the INTER-assay variation (6.5%).

**Quantification procedure and statistical analysis**

Quantitative analysis of the autoradiographic films was performed using a computerized analysis system (Biocom-program RAG 200). Total optical density (OD) was measured for each region of interest (MR, DR). The surface of each region was measured and the area of TPH2 mRNA expression was found to be comparable between the experimental groups. Non-specific OD was subtracted from total OD. By reference to radioactive
microscales, OD was converted to relative levels of mRNA. Based on previous studies [5–8], the well-known anatomical limits and subdivisions for the DR nuclei [23] were considered in the present study, so the DR was divided into three distinguishable subgroups in which TPH2 mRNA levels were quantified separately: ventromedial (VM), dorsomedial (DM) and lateral (LAT).

One-way analysis of variance (ANOVA I, time as factor) was conducted in order to examine the daily variation of melatonin plasma levels and TPH2 mRNA expression in the MR and all the DR subdivisions for both LP and SP animals and was followed by a Post-Hoc Newman-Keuls analysis. On the other hand, two-way analysis of variance (ANOVA II, photoperiodic condition and time as factors) and Newman-Keuls analysis were performed to compare the daily profiles of TPH2 mRNA between LP and SP condition. For all statistical procedures, the level of significance was set at $p < 0.05$.

**Results**

**Plasma melatonin levels**

Plasma melatonin concentrations display noticeable daily variations under both LP and SP conditions (Figure 1, $p < 0.01$ for both photoperiods). The melatonin peak is delayed with the increase of the night length. Under LP, the nocturnal rise of melatonin occurs within $3\,\text{h}$ after the lights are off (02h00) and expands on the following $2\,\text{h}$ (04h00). The nocturnal rise under SP occurs about $10\,\text{h}$ after the lights are off (06h00) and lasts for the rest of the night period. These profiles are in accordance with previous results obtained in the rat and confirm the integration of the photoperiodic change [17, 18].

**Effect of photoperiod on TPH2 mRNA in the MR**

The daily pattern of TPH2 mRNA expression in MR of rats housed under LP and SP is presented in Figure 2. The ANOVA I analysis reveals significant daily variation of TPH2 mRNA expression in MR under both photoperiodic conditions ($p < 0.05$ for both LP and SP). A sharp increase (93%) in TPH2 mRNA levels in MR is observed at the night/day transition in LP group ($p < 0.05$ between 04h00 and 09h00). On the other hand, a significant decrease in TPH2 mRNA levels is noticed during the night under LP (24h00/04h00: –81%, $p < 0.05$). In all the daytime points, TPH2 mRNA expression exhibits no significant difference compared with 24h00. In rats of the SP group, the maximal expression levels are also observed during the daytime ($p < 0.05$ between 13h00 and 18h00). The percentage of the increase between these two time-points is 40%. During the dark period, TPH2 mRNA

![Figure 1. Daily profiles of melatonin plasma concentrations (pg/ml) measured by radioimmunoassay in rats housed under long (LP18:6, blue triangles) and short (SP6:18, red circles) photoperiods. Each symbol corresponds to the mean±SEM of four rats. The coloured horizontal bars represent the length of night period (blue bar for SP, red bar for LP). Using ANOVA I, *** $p < 0.001$ and ** $p < 0.01$ for the time effect on melatonin plasma levels in LP and SP rats, respectively.](image1)

![Figure 2. The daily profiles of TPH2 mRNA levels in the median raphe (MR) of rats housed under long (LP18:6, blue triangles) and short (SP6:18, red circles) photoperiods. The top panel illustrates TPH2 mRNA in situ hybridization within the MR (scale bar: 1000 μm). Each symbol is the mean±SEM of four rats in which TPH2 mRNA was quantified throughout the caudo-rostral extent of the MR. The coloured horizontal bars represent the length of night period (blue bar for SP, red bar for LP). * $p < 0.05$, using ANOVA I to assess the effect of the timing on the daily expression of TPH2 mRNA.](image2)
expression levels remain unchanged. Comparing the daily pattern of TPH2 mRNA in both photoperiods (ANOVA II) reveals no significant effect for time or photoperiod, though a significant interaction between both factors is observed ($p < 0.001$). The latter analysis demonstrates that the daily profile of TPH2 mRNA is different between LP and SP group.

**Effect of photoperiod on TPH2 mRNA in the DR**

The daily pattern of TPH2 mRNA expression in the DR subgroups is presented in Figure 3 and is indeed quite similar to that reported in MR. TPH2 mRNA expression levels are quantified separately in each subgroup of the DR: VM, DM and LAT (Figure 3). In the DR, the expression of TPH2 mRNA displays significant daily variations under LP ($p < 0.05$ for VM, $p < 0.01$ for DM and LAT) and SP ($p < 0.01$ for VM and LAT, $p < 0.05$ for DM). A marked increase of TPH2 mRNA expression occurs between 04h00 and 09h00 under LP condition in the DR (90% for VM, 100% for DM and 92% for LAT, $p < 0.01$ for all the subgroup). Under the same photoperiod, a significant nocturnal decrease of TPH2 mRNA levels is observed between 24h00 and 04h00 for VM ($–79\%$, $p < 0.05$) and LAT ($–78\%$, $p < 0.01$). In the DM, however, this decrease ($–66\%$) fails to reach the significance limit. No significant differences are noted between 24h00 and other daytime points in all DR subgroups. Under SP, the highest levels of TPH2 mRNA are reported at 18h00 ($p < 0.05$ for VM and DM and $p < 0.01$ for LAT, between 13h00 and 18h00). The percentage of the 13h00/18h00 increase is 38% for VM, 33% for LAT and 52% for DM. For all night-time points, TPH2 mRNA expression levels are unchanged. The statistical comparison of TPH2 mRNA daily profiles between LP and SP condition in DR showed no significant differences in either time, except for VM ($p < 0.001$), or photoperiod. The interaction between both factors is however significant ($p < 0.01$ for VM, $p < 0.001$ for DM and LAT), which demonstrate that the daily pattern of TPH2 mRNA expression is different with respect to the photoperiod.

**Discussion**

To our knowledge, this is the first evidence for photoperiod-related changes in the daily pattern of the tph2 gene expression in rats. Under standard lighting conditions (i.e. LD12:12), TPH2 mRNA undergoes rhythmic expression and the higher levels are observed 2 h before the light/dark transition in both raphe nuclei [7]. In this study, we report a similar expression pattern under SP8:16, where TPH2 mRNA levels peak at 18h00 (lights off at 20h00) in both MR and DR. This is however different to that in LP group, for which TPH2 mRNA levels peak at the beginning of the light period and are unaffected by the light/dark transition. Under both photoperiodic conditions, TPH2 mRNA levels increase with the lights on, which might reflect an effect of the light onset on its expression. Previous tract tracing studies have described the presence of
retinal input to the DR, suggesting that 5-HT neurons can receive the light/dark information [24, 25]. The effect of light on TPH2 mRNA expression needs to be further investigated. On the other hand, our previous findings demonstrate a clear control of SCN on the TPH daily patterns since the day/night rhythm is preserved in animals housed under constant darkness for 48 h before decapitation [6, 7]. It is important to determine whether the serotonergic neurons are directly sensitive to light duration or indirectly responding through SCN photoperiodic mediators.

It is noteworthy that the daily pattern of TPH2 mRNA under LP tends to be bimodal because the expression levels display a marked nocturnal decrease in DR and MR before the peak at the beginning of the light period. This bimodal pattern is, however, not evident in VM and DM, and the nocturnal decrease of TPH2 mRNA levels in the latter subgroup is not significant. A bimodal pattern in serotonergic neurons has been previously reported in rats under LD12:12 conditions concerning 5-HT content in the raphe [26] as well as TPH protein content in the SCN [5]. However, in the latter study, the bimodal pattern was not found in the daily profile of 5-HT release in the SCN, which displays a single peak at the beginning of the dark period.

In our previous studies, we have described a temporal relationship between TPH2 mRNA, TPH protein and 5-HT release in the rat circadian system under standard lighting conditions [5–7]. Indeed, these three parameters display rhythm and time-related variations under LD12:12 cycle. The circadian variations of TPH2 mRNA in the DR and MR are found at the protein level in the same nuclei, as well as in the 5-HT terminals within the SCN and the IGL [5–7]. Furthermore, the 5-HT release is rhythmic in the SCN [5, 9, 10] and the IGL [11]. In this study, TPH2 mRNA variations in DR were observed in all the subdivisions with a remarkable similarity, which is consistent with our previous findings [7]. This however was not the case for the TPH protein pattern reported in early study where only the lateral parts of the DR showed rhythmicity [6], which raises the question whether there is a post-transcription modification on TPH2 mRNA only in DM and VM specially that early tract tracing studies showed that the main Serotonin input to the circadian structures originates from the lateral parts of DR [23]. Herein, we demonstrate a daily differential pattern of TPH2 mRNA expression in both DR and MR concerning photoperiodic environment. It could be suggested that the rhythmic patterns of TPH protein levels and 5-HT release would display photoperiod-related changes within both RD-IGL and RM-SCN pathways. Further experiments should be done in order to confirm such hypothesis.

We have previously demonstrated that TPH2 mRNA expression under constant darkness displays variations similar to those observed under LD12:12, indicating a circadian regulation of this expression [7]. This later result confirms that TPH2 mRNA daily pattern is under the SCN clock control. The rhythmic expression of TPH2 mRNA has been shown to be controlled by glucocorticoids [8], one of the endocrine outputs of the SCN central pacemaker [20–22]. In rats, the daily secretion of corticosterone is affected by the day-length [22] and could thereby provide an internal signal not only for the circadian time but also for the seasonal time. Glucocorticoids might thus drive the photoperiod-related changes in TPH2 mRNA described in the present study. To further confirm the involvement of corticosterone, it would be relevant to examine photoperiodic variations of TPH2 mRNA after removing the adrenal glands. Furthermore, we can investigate the influence of photoperiodic changes upon GR expression levels within both DR and MR, to assess whether the sensitivity of the serotonergic neurons to corticosterone is modified according to the photoperiod.

On the other hand, melatonin secretion is a seasonal output of the SCN known to drive photoperiodic message. Indeed, the duration of the nocturnal melatonin secretion is proportional to the length of darkness, providing an internal signal for seasonal changes [17, 18]. A primary target tissue of this seasonal signal in mammals is the hypophyseal pars tuberalis in which melatonin is a key regulator of clock genes expression [27–30]. Melatonin could also be involved, as a seasonal signal, in the photoperiodic changes of TPH2 mRNA daily rhythm reported in the present study. Although melatonin receptors have not been identified in the raphe neurons [31,32], this hormone has been shown to modulate 5-HT synthesis in the SCN [33]. It can be suggested that melatonin would act indirectly upon the serotonergic neurons via melatonin-sensitive brain areas. Despite the fact that the expression patterns for both melatonin and TPH2mRNA are not similar, the physiological effect of the hormone could be mediated by other photoperiodic actors under melatonin control, and that would explain the observed shift between both profiles. To further investigate the melatonin hypothesis, the present photoperiodic profiles must be studied after removing the pineal gland.
Conclusion

Our overall results lead us to conclude that the raphe serotonergic neurons are sensitive to changes in the photoperiodic environment. The daily pattern of TPH2 mRNA is affected by these changes, which might influence TPH protein levels and 5-HT release within the SCN. If so, the involvement of the serotonergic system in the photoperiodic time measurement should be further considered. Moreover, photoperiodic changes in 5-HT release within the SCN, and elsewhere in the brain, would reflect the involvement of the serotonergic system in seasonal affective disorder.
