Efficacy and safety of paracetamol for spinal pain and osteoarthritis: systematic review and meta-analysis of randomised placebo controlled trials

Gustavo C Machado,1 Chris G Maher,1 Paulo H Ferreira,2 Marina B Pinheiro,2 Chung-Wei Christine Lin,1 Richard O Day,3,4 Andrew J McLachlan,5,6 Manuela L Ferreira1,7

ABSTRACT
OBJECTIVE
To investigate the efficacy and safety of paracetamol (acetaminophen) in the management of spinal pain and osteoarthritis of the hip or knee.

DESIGN
Systematic review and meta-analysis.

DATA SOURCES
Medline, Embase, AMED, CINAHL, Web of Science, LILACS, International Pharmaceutical Abstracts, and Cochrane Central Register of Controlled Trials from inception to December 2014.

ELIGIBILITY CRITERIA FOR SELECTING STUDIES
Randomised controlled trials comparing the efficacy and safety of paracetamol with placebo for spinal pain (neck or low back pain) and osteoarthritis of the hip or knee.

DATA EXTRACTION
Two independent reviewers extracted data on pain, disability, and quality of life. Secondary outcomes were adverse effects, patient adherence, and use of rescue medication. Pain and disability scores were converted to a scale of 0 (no pain or disability) to 100 (worst possible pain or disability). We calculated weighted mean differences or risk ratios and 95% confidence intervals using a random effects model.

RESULTS
12 reports (13 randomised trials) were included. There was “high quality” evidence that paracetamol is ineffective for reducing pain intensity (weighted mean difference −0.5, 95% confidence interval −2.9 to 1.9) and disability (0.4, −1.7 to 2.5) or improving quality of life (0.4, −0.9 to 1.7) in the short term in people with low back pain. For hip or knee osteoarthritis there was “high quality” evidence that paracetamol provides a significant, although not clinically important, effect on pain (−3.7, −5.5 to −1.9) and disability (−2.9, −4.9 to −0.9) in the short term. The number of patients reporting any adverse event (risk ratio 1.0, 95% confidence interval 0.9 to 1.1), any serious adverse event (1.2, 0.7 to 2.1), or withdrawn from the study because of adverse events (1.2, 0.9 to 1.5) was similar in the paracetamol and placebo groups. Patient adherence to treatment (1.0, 0.9 to 1.1) and use of rescue medication (0.7, 0.4 to 1.3) was also similar between groups. “High quality” evidence showed that patients taking paracetamol are nearly four times more likely to have abnormal results on liver function tests (3.8, 1.9 to 7.4), but the clinical importance of this effect is uncertain.

CONCLUSIONS
Paracetamol is ineffective in the treatment of low back pain and provides minimal short term benefit for people with osteoarthritis. These results support the reconsideration of recommendations to use paracetamol for patients with low back pain and osteoarthritis of the hip or knee in clinical practice guidelines.

SYSTEMATIC REVIEW REGISTRATION
PROSPERO registration number CRD42013006367.

Introduction
Low back and neck pain (spinal pain) are leading causes of disability worldwide, and osteoarthritis of the hip or knee is the 11th highest contributor to global disability, when disability is measured by years lived with disability.1 The point prevalence of spinal pain is 9.4%, and osteoarthritis affects nearly 4% of the global population.2–4 The increasing healthcare expenditure for these conditions is mostly attributed to the increasing cost of prescription medicines, accounting for about 20% of the total cost.5

Prescription of drugs is the most common approach to treatment used by general practitioners for spinal pain and osteoarthritis,6 and guidelines consistently recommend the prescription of paracetamol (acetaminophen) as the first line analgesic for these conditions.7–11 There has, however, been controversy about keeping paracetamol in the most recent guidance on osteoarthritis from the National Institute for Health and Care...
Excellence, mainly because of previous studies reporting small effects of paracetamol compared with placebo. Moreover, optimal therapeutic benefits of paracetamol might require regular doses of up to 4000 mg/day. There are some concerns regarding safety of the full recommended dose, although the evidence on safety is still debatable. Potential adverse effects and treatment schedule seem to also have a considerable effect on patient adherence as taking analgesics constantly and regularly three or four times a day is inconvenient at least.

New randomised controlled trials have been conducted since the last meta-analyses of paracetamol for spinal pain and osteoarthritis of the hip or knee were published. There is still uncertainty, however, whether consideration of new data changes the conclusions regarding the efficacy and safety of paracetamol for these conditions. In this systematic review we investigated the efficacy and safety of paracetamol in patients with spinal pain or osteoarthritis of the hip or knee by including data from placebo controlled trials only, as these represent the highest standard of evidence to inform the optimal use of drugs.

Methods

Data sources and searches
We conducted a systematic review following the PRISMA statement and prospectively registered the review on PROSPERO. We carried out a systematic electronic search in Medline, Embase, AMED, CINAHL, Web of Science, LILACs, International Pharmaceutical Abstracts, and Cochrane Central Register of Controlled Trials from inception to 8 December 2014. We used a combination of relevant keywords to construct the search strategy including paracetamol, acetaminophen, back pain, neck pain, osteoarthritis, osteoarthrosis, placebo, randomised, and controlled trial (see appendix 1). One author (GCM) conducted the first screening of potentially relevant records based on titles and abstract, and two authors (GCM and MBP) independently performed the final selection of included trials based on full text evaluation. Citation tracking was also performed on included studies and relevant systematic reviews, and relevant websites and clinical trials registries were searched for unpublished studies. Consensus between the two reviewers was used to resolve any disagreement.

Study selection
We included only randomised controlled trials comparing the efficacy of paracetamol versus placebo. To be eligible, trials had to include participants with non-specific spinal pain (neck or low back pain) or osteoarthritis of the hip or knee. We did not exclude trials in mixed populations of patients with spinal pain and osteoarthritis. The intensity and duration of symptoms were not restricted. There were also no restrictions for languages or publication date. Studies that included patients with a serious spinal pathology (such as cauda equina syndrome, tumour, or infection) were excluded. Studies with mixed populations of patients with rheumatoid arthritis and osteoarthritis were also excluded, unless separate data were reported for osteoarthritis. Studies in which participants had previous spinal, hip, or knee surgery remained eligible, but trials evaluating analgesia in the immediate postoperative period were not included. We included only full reports in this systematic review (that is, no abstracts).

Trials were eligible for inclusion when they reported at least one of the following primary outcome measures: pain intensity, disability status, and quality of life. Secondary outcome measures were safety (adverse effects), patient adherence, and use of rescue medication.

Data extraction and quality assessment
Using a standardised data extraction form, two reviewers (GCM and MBP) independently extracted study characteristics (details of participants, interventions, and outcomes) from the included trials, and a third author (MLF) resolved any disagreement. We extracted means, standard deviations, and sample sizes for our primary outcome measures. Mean estimates were extracted in the following hierarchical order: mean differences, change scores, and final values. For our secondary outcomes, we extracted the number of cases and the total sample size. The safety outcomes extracted from included trials were the number of patients reporting any adverse event, the number of patients reporting any serious adverse event (as defined by each study), the number of patients withdrawn from study because of adverse events, and the number of patients with abnormal results on liver function tests (hepatic enzyme activity ≥1.5 times the upper limit of the reference range). We contacted authors to provide further information when there were insufficient data reported in the paper. When authors were unavailable we estimated data using the recommendations in the Cochrane Handbook for Systematic Reviews of Interventions.

Two reviewers (GCM and MBP) independently assessed the risk of bias of the included studies using the Cochrane Collaboration’s tool. Consensus was used to resolve any disagreement. RevMan version 5.3.5 was used to generate figures and summaries. The quality of evidence was rated for each pooled analysis with the GRADE (grading of recommendations assessment, development and evaluation) system, with outcomes of interest being ranked according to their relevance for clinical decision making as of limited importance, important, or critical. The quality of evidence was downgraded by one level according to the following criteria: limitation of study design, inconsistency of results, imprecision, and publication bias. We did not consider the indirectness criterion in this review because we included a specific population with relevant outcomes and direct comparisons. Briefly, GRADE was downgraded by one level for limitation of study design when more than a quarter of the studies included in an analysis were considered at high risk of bias (that is, one or more bias domains were judged as high risk) according to the Cochrane Handbook and thus plausible to affect the interpretation of our results. Results were considered inconsistent if there
was a wide variance of point estimates across studies or if the heterogeneity between trials was large (P > 50%).

Imprecision was identified when the upper or lower limits of the 95% confidence interval crossed the minimal clinically important difference of 9 points (range 0–100). We visually judged a funnel plot (scatterplot of the effect of estimates from individual studies against its standard error) and used Egger’s test to investigate publication bias (small study effects). We included a total of 11 trials in the assessment of small study effects (nine trials including patients with osteoarthritis and two trials including patients with back pain, reporting data on immediate or short term pain intensity). If the Egger’s test result was significant (two tailed P < 0.1) we would downgrade the quality of evidence (GRADE) by one level for all meta-analyses. The quality of evidence was defined as “high quality,” “moderate quality,” “low quality,” and “very low quality.”

**Data synthesis and analysis**

We grouped the outcomes into four time points of assessment: immediate term (≤ 2 weeks), short term (> 2 weeks but ≤ 3 months), intermediate term (> 3 months but ≤ 12 months), and long term (> 12 months). If studies reported multiple time points within each category, we used the time point closest to one week for immediate term, eight weeks for short term, six months for intermediate term, and 12 months for long term. When studies reported more than one scale to measure pain we extracted the more severe estimate reported at baseline. Scores for pain and disability were converted to a common 0 (no pain or disability) to 100 (worse pain or disability) scale. Pain intensity measures to calculate treatment effects were numerical rating scale scores (range 0–10) or visual analogue scale scores (range 0–100). These two pain measures are highly correlated and can be used interchangeably when transformed. Other measures of pain were also obtained from visual analogue scale scores included in the Western Ontario and McMaster Universities osteoarthritis index (WOMAC) pain subscale (VA3 series range 0–100) and from the multi-dimensional health assessment questionnaire (MDHAQ) pain subscale (range 0–100). Disability measures in the meta-analyses were WOMAC function subscale or WOMAC total scores. One study reported pain and disability measures from the WOMAC Likert version (LK series), and the scores were also normalised to a scale of 0 to 100.

To facilitate the interpretation of our pooled estimates, we defined the effects of paracetamol compared with placebo as ineffective when the 95% confidence interval crossed the no effect line, showing no significant difference between groups. We considered the minimal clinically important difference as a difference of 9 mm in a 0–100 mm visual analogue scale. This estimate has been used in past systematic reviews to investigate the efficacy of medicines compared with placebo for osteoarthritis and corresponds to the median minimal clinically important difference found in trials investigating patients with osteoarthritis. When our treatment effects were smaller than 9 mm, although significant, we considered the effect as small and not clinically important.

We used the I² statistic to assess heterogeneity between trials, and values higher than 50% were defined to identify high heterogeneity. We calculated weighted mean differences or risk ratios and 95% confidence intervals and used the random effects model to pool estimates for each analysis obtained with Comprehensive Meta-Analysis version 2.2.064 (Englewood, NJ, 011).

**Secondary exploratory analysis**

We performed sensitivity analyses to explore the influence of each risk of bias domain on pooled treatment effects. These stratified analyses were accompanied by meta-regression to generate a P value for interaction between the bias domain and estimate of treatment effect. For these analyses we used data from all osteoarthritis trials included in the meta-analysis on short term pain (seven trials). As a previous study reported that small trials in osteoarthritis tend to report more beneficial treatment effects than large trials, we also conducted a sensitivity analysis between large trials (sample size ≥100 per group) versus small trials (sample size <100 per group) for all trials investigating patients with osteoarthritis at immediate or short term follow-up. Negative differences in treatment effects indicate that small trials have more beneficial effects than large trials.

**Post hoc analysis**

We carried out a post hoc analysis to assess the potential impact of a new trial on the current evidence and thus to determine if a new trial is justified. We used extended funnel plots (graphical augmentations of the funnel plots commonly used to investigate publication bias in meta-analyses) to assess the impact of a new trial in our meta-analysis. The extended funnel plots provide shaded contours that represent the contribution of a new trial to existing evidence based on statistical simulations. Addition of data from a new trial of a certain sample size and treatment effect could

---

**Fig 1** Flow chart of trials investigating efficacy of paracetamol in spinal pain and osteoarthritis. Numbers of records from each database include duplicates. IPA=International Pharmaceuticals Abstracts, CENTRAL=Cochrane Register of Controlled Trials
result in the new conclusion that the effect of intervention is clearly worthwhile or clearly not worthwhile, for instance. We conducted extended funnel plots to assess the impact a further trial of paracetamol for spinal pain and hip or knee osteoarthritis would have on the current evidence presented in this meta-analysis. Stata 13 (StataCorp, College Station, TX) was used for this analysis.

**Results**

Our search results yielded 5498 records, and after excluding duplicates we screened 4037 titles and abstracts. Two independent reviewers evaluated 116 potentially relevant studies, and 12 records (13 randomised controlled trials) met the criteria to be included in this review, with one article reporting results of two trials (fig 1).41-54 Ten trials reporting data from 3541 patients evaluated the efficacy of paracetamol in patients with osteoarthritis of the hip or knee,43,44,46-51,55, and three trials (1825 patients) investigated the efficacy of paracetamol in people with low back pain.45,52,53 We did not identify any trials in patients with neck pain. Overall, the included trials assessed 5366 patients. We identified two randomised trials published as abstracts and excluded them from this review.55,56 One randomised trial investigating the efficacy of paracetamol for low back pain did not report results for the placebo group, and attempts to access these data from the authors and the company that funded the study were unsuccessful.45 This trial was included in the review but not in the meta-analysis.

In the included studies paracetamol was primarily administered orally (as tablets/capsules). One trial, however, reported the use of intravenous paracetamol in participants with chronic low back pain.52 The total oral dose and doses regimens for paracetamol varied across trials, with 10 trials using a total dose of 3900–4000 mg/day and three trials using 3000 mg/day (table 1). Two trials used a three arm design, one

| Table 1 | Characteristics of randomised placebo controlled trials included in review of efficacy and safety of paracetamol for spinal pain and osteoarthritis |
|---------|------------------------------------------------------------------------------------------------------------------------------------------|
| Study   | Details of participants | Interventions (Dose regimens)                                                                 | Outcomes and time points                                                                 |
| Spinal pain |                                                                    |                                                                                             |                                                                                          |
| Nadler, 200245 | 133 patients (group 1=113, group 2=20); mean age (SD) group 1=34.9 (11.3), group 2=38.0 (9.1), duration: acute (NR) | Group 1: paracetamol 500 mg, 2 tablets, 4 times daily, 4000 mg total. Group 2: oral placebo | Pain (VRS, 0–5); Roland Morris questionnaire (0–24); adverse events; on days 2 and 4 |
| Wetzel, 201442 (cross over) | 40 patients on chronic opioid therapy, mean age (SD) group 1=57.2 (12.8), duration: chronic (6 months) | Group 1: single intravenous paracetamol 1000 mg dose. Group 2: intravenous placebo | Pain (VAS, 0–10); Roland Morris questionnaire (0–24); immediately after infusion |
| Williams, 201453 | 1652 patients (group 1=550, group 2=549, mean age (SD) group 1=44.1 (14.8), group 2=54.5 (16.7), duration: acute (6 weeks) | Group 1: paracetamol 665 mg, 2 tablets, 3 times daily, 3990 mg total. Group 2: paracetamol 500 mg, 1–2 tablets as required, 4–6 hours apart, maximum 8 tablets per day. Group 3: oral placebo. Rescue medication allowed | Pain (NRS, 0–10); Roland Morris questionnaire (0–24); SF-12 physical score (0–100); patient adherence; rescue medication; adverse events; at 1, 2, 4, and 12 weeks |
| Osteoarthritis |                                                                    |                                                                                             |                                                                                          |
| Amadio, 198351 (cross over) | 25 patients; median age (range)=64 (43–80), duration: NR | Group 1: paracetamol 500 mg, 2 tablets, 4 times daily, 4000 mg total. Group 2: oral placebo | 50 ft (15 m) walking test, adverse events; at 4 weeks |
| Zoppi, 199554 | 60 patients (group 1=30, group 2=30); mean age (SD) group 1=57.6 (11.2), group 2=55.3 (11.9), duration: group 1=75.0 (98.2) months, group 2=65.4 (58.6) months | Group 1: effervescent paracetamol 500 mg, 2 tablets, 3 times daily, 3000 mg total. Group 2: efervescence placebo | Pain (VAS, 0–100); adverse events; at 1 week |
| Case, 200344 | 57 patients (group 1=29, group 2=28); mean age (SD) group 1=62.1 (11.4), group 2=61.7 (9.0), duration: NR | Group 1: paracetamol 500 mg, 2 tablets, 4 times daily, 4000 mg total. Group 2: oral placebo | WOMAC pain (VAS, 0–50); WOMAC function (0–1700); adverse events; at 2 and 12 weeks |
| Golden, 200457 | 303 patients (group 1=148, group 2=155); mean age (SD) group 1=61.1 (13.1), group 2=60.3 (13.0), duration: NR | Group 1: paracetamol 1000 mg, 1 tablet, 4 times daily, 4000 mg total. Group 2: oral placebo | Pain intensity on walking bearing (0–4); 50 ft (15 m) walking test; adverse events; at 1 week |
| Miceli-Richard, 200468 | 779 patients (group 1=405, group 2=374); mean age (SD)=70 (11), duration: 46.4 (47) months | Group 1: paracetamol 1000 mg, 1 tablet, 4 times daily, 4000 mg total. Group 2: oral placebo | Pain (VAS, 0–100); WOMAC function (0–100); adverse events; patient adherence; at 1 and 6 weeks |
| Pincus, 2004a (PACES-A cross over trial)59 | 524 patients; mean age (SE) group 1=63.7 (1.2), group 2=62.8 (1.3); duration group 1: 8.5 (1.0) years, group 2: 8.1 (1.1) years | Group 1: Paracetamol 1000 mg, 1 tablet, 4 times daily, 4000 mg total. Group 2: oral placebo. Rescue mediation not allowed | MDHAQ pain (VAS, 0–100); WOMAC (0–100); adverse events; at 6 weeks |
| Pincus, 2004b (PACES-B cross over trial)59 | 556 patients; mean age (SE) group 1=64.8 (1.3), group 2=63.4 (1.3); duration group 1: 10.4 (1.3) years, group 2: 9.5 (1.1) years | Group 1: paracetamol 1000 mg, 1 tablet, 4 times daily, 4000 mg total. Group 2: oral placebo. Rescue medication allowed | MDHAQ pain (VAS, 0–100); WOMAC (0–100); adverse events; at 6 weeks |
| Herrero-Beaumont, 200750 | 212 patients (group 1=108, group 2=104); mean age (SD) group 1=63.8 (7.2), group 2=64.5 (6.9); duration: group 1: 6.5 (5.3) years, group 2: 7.2 (5.8) years | Group 1: paracetamol 1000 mg, 1 tablet, 3 times daily, 3000 mg total. Group 2: oral placebo. Rescue medication allowed | WOMAC pain (Likert, 0–20); WOMAC function (0–68); rescue medication; adverse events; at 6 months |
| Altman, 200750 | 483 patients (group 1=160, group 2=158, mean age (range)=62.2 (40–90), duration: NR | Group 1: paracetamol ER 1300 mg, 3 times daily, 3990 mg total. Group 2: paracetamol 650 mg, 3 times daily, 1950 mg total. Group 3: oral placebo. Rescue medication allowed | WOMAC pain (VAS, 0–100); WOMAC function (0–100); adverse events; at 12 weeks |
| Prior, 201449 | 542 patients (group 1=267, group 2=275); mean age (SD) group 1=61.7 (10.2), group 2=61.7 (10.1), duration: NR | Group 1: paracetamol ER 650 mg, 2 tablets, 3 times daily, 3990 mg total. Group 2: oral placebo. Rescue medication allowed; but limited | WOMAC pain (VAS, 0–100); WOMAC function (0–100); adverse events; at 2 and 12 weeks |

VRS=verbal rating scale, VAS=visual analogue scale, NRS=numeric rating scale, NR=not reported, WOMAC=Western Ontario and McMaster Universities arthritis index, MDHAQ=multiparameter health assessment questionnaire, SF-12=12-item short form health survey, Duration=duration of condition, ER=extended release.
included a third group that received paracetamol as required, and another included a third group that received a lower dose of paracetamol (650 mg, one tablet, three times/day, 1950 mg total). All three treatment groups were included in the meta-analyses following the recommendation in the Cochrane Handbook for Systematic Reviews of Interventions. The washout period before treatment started varied across trials, ranging from one day to six months. The washout periods were 12 weeks for corticosteroids, six weeks for intra-articular steroids, and ranged from three days to two weeks for non-steroidal anti-inflammatory agents. Patients stopped taking simple analgesics from one to 10 days. One trial reported that the washout for glucosamine drugs was six months, and two trials used “five half lives” to define this period.

We included six trials that reported data from people with chronic pain, and two studies that included people with acute pain only. The remaining studies did not report the duration of pain or disability. Nine trials used the diagnosis of osteoarthritis based on image evidence and clinical assessment, whereas one trial based the diagnosis solely on image evidence. Two trials used a clear definition of low back pain, and one trial used a simple question to define patients (“do the muscles of your low back hurt?”). Table 1 includes more detailed information on included trials.

Figure 2 summarises the assessment of risk of bias for individual trials. Twelve trials had at least one domain judged as unclear risk of bias. Four trials had at least one domain considered as high risk of bias, and only one trial had all bias domains judged as low risk of bias. Most trials (nine) failed to report the method used to generate the sequence allocation, though all reported being randomised studies. Three trials adopted an appropriate method of concealment of allocation, and only one trial failed to report blinding of patients, personnel, and outcome assessors. Eight trials were funded by companies that produce paracetamol and were considered as having unclear risk of bias for the other sources of bias domain. As only one study reported data for intermediate term follow-up, its results were pooled with trials reporting data for short term follow-up. None of the included trials reported data for long term follow-up. The inspection of the funnel plot and the lack of significance of the Egger’s test (P=0.21) suggested no serious small study effects (see appendix 2, fig A). We therefore considered that no meta-analysis presented serious publication bias according to the GRADE approach. Figure 3 summarises pooled effect sizes for pain and disability at immediate and short term follow-up. Tables 2 and 3 present individual trial results and calculations of effect sizes.

**Spinal pain**

**Immediate term follow-up**

Two trials including 1692 patients with low back pain tested the effect of paracetamol compared with placebo in pain reduction. Pooling showed no effect of paracetamol on pain (weighted mean difference 1.4, 95% confidence interval −1.3 to 4.1; “moderate quality” evidence, downgraded for limitation of study design). For disability, one trial evaluating 1652 patients found no difference between paracetamol and placebo (−1.9, −4.8 to 1.0). The quality of evidence for disability in the immediate term was rated “high quality” according to the GRADE approach.

**Short term follow-up**

Only one trial investigated the short term efficacy of paracetamol in 1652 patients with low back pain. This trial showed no effect of paracetamol on pain intensity (weighted mean difference −0.5, 95% confidence interval −2.9 to 1.9), disability (0.4, −1.7 to 2.5), or quality of life measured by the 12-item short form health survey (SF-12 version 2) (0.4, −0.9 to 1.7) at short term follow-up. The quality of evidence (GRADE) for
all three outcomes was rated as “high quality.” Tables 4 and 5 summarise the findings and quality assessment (GRADE) for outcomes ranked as critical for decision making.

**Osteoarthritis**

**Immediate term follow-up**

Five trials reported data from 1741 patients with hip or knee osteoarthritis and were included in a meta-analysis.
to evaluate the immediate effect of paracetamol in pain reduction.\textsuperscript{44, 46–48, 54} Pooling showed that paracetamol has a small benefit when compared with placebo in reducing pain (weighted mean difference $-3.3$, $-5.8$ to $-0.8$; “high quality” evidence). For disability, pooling of three trials with 1378 patients showed no immediate effect of paracetamol ($-1.7$, $-6.0$ to $2.6$; “moderate quality” evidence, downgraded for inconsistency).\textsuperscript{56, 46–48, 54}

**Short term follow-up**

At short term follow-up, seven trials including 3153 patients with hip or knee osteoarthritis were pooled to estimate the efficacy of paracetamol in reducing pain and disability.\textsuperscript{46–48, 54} Pooling showed a significant small effect favouring paracetamol for pain (weighted mean difference $-3.7$, $-5.5$ to $-1.9$). Similarly, a significant but small benefit of paracetamol was found for short term reduction in disability ($-2.9$, $-4.9$ to $-0.9$). The quality of evidence (GRADE) for both pooling was rated as “high quality.”

**Secondary outcomes**

Our secondary outcomes included adverse effects, patient adherence, and use of rescue medication. Fig 4 summarises the results.

**Adverse effects**

The type of adverse events reported by patients varied substantially between trials. Nine trials investigated the number of participants reporting any adverse event.\textsuperscript{43, 44, 47–50, 53, 54} There was no difference in the number of patients reporting adverse events between the paracetamol and placebo groups (risk ratio 1.0, 0.9 to 1.1; “moderate quality” evidence). The number of patients reporting any serious adverse event (as defined by each study) was also similar in both paracetamol and placebo groups (1.2, 0.7 to 2.1; “moderate quality” evidence).\textsuperscript{46–51, 53, 54} Ten trials reported data on the number of patients withdrawn from the study because of adverse events, with three of these trials reporting no drop outs from adverse events. We found no significant difference between groups for this outcome (1.2, 0.9 to 1.5; “high quality” evidence).\textsuperscript{44, 46–48, 51–56} Three trials evaluated the results of liver function tests to detect adverse effects of paracetamol (activities of alanine aminotransferase, and/or aspartate aminotransferase) in participants with osteoarthritis.\textsuperscript{50, 51, 54} Where an abnormal test was defined as hepatic enzyme activity 1.5 times the upper limit of the reference range or over. Pooling showed that participants taking paracetamol are nearly four times more likely to have abnormal results on liver function tests than participants taking placebo (3.8, 1.9 to 7.4; “high quality” evidence).

**Patient adherence**

Two trials in patients with low back pain and osteoarthritides investigated adherence to study treatments, defined as the number of patients reporting consumption of more than 70\%\textsuperscript{53} or 85\%\textsuperscript{48} of the recommended dose. We found no difference in the number of participants adhering to study treatments between paracetamol and placebo groups from the pooling of two trials (risk ratio 1.0, 0.95 confidence interval 0.9 to 1.1; “moderate quality” evidence, downgraded for inconsistency).

**Use of rescue medication**

This was measured as the number of patients using a rescue medication (naproxen 250 mg, two tablets initially then one tablet every six to eight hours as needed,\textsuperscript{53} or ibuprofen 400 mg, one tablet every eight hours for a maximum of three days\textsuperscript{51}) during the trial. Pooled analysis of two trials in low back pain and osteoarthritis showed no difference between the paracetamol and placebo groups (risk ratio 0.7, 95\% confidence interval 0.4 to 1.3; “high quality” evidence).

**Secondary exploratory analysis**

The results from our secondary analyses on the potential impact of individual risk of bias domains on our
Calculation of effect sizes for immediate and short term pain and disability outcome measures in people with osteoarthritis randomised to paracetamol or placebo

treatment effects are presented in fig B in appendix 2. None of the individual domains had a significant influence on the estimated treatment effect. Our stratified analysis between small and large trials showed a difference of effects of 1.4 (95% confidence interval −2.8 to 5.6), indicating that smaller trials tend to report less beneficial effects, though this difference was not significant (P=0.51).

Extended funnel plot assessment
After consideration of the results we carried out a post hoc analysis to assess the effect of a new trial in our meta-analysis using extended funnel plots. Our results confirm that the results of a new trial added to current evidence would not change the conclusion that paracetamol does not deliver a clinically important benefit (at least 9 points out of a 0–100 range) for spinal pain and osteoarthritis (see fig C in appendix 2).

Discussion
There is “high quality” evidence that paracetamol has a significant but small effect in patients with hip or knee osteoarthritis compared with placebo in the short term. The small effects, <4 points on a 0–100 point scale, are not likely to be meaningful for clinicians or patients. “High quality” evidence shows that paracetamol is ineffective for low back pain, but we found no trials investigating neck pain. We also found “high quality” evidence that paracetamol increases the risk of having an abnormal result on liver function tests by nearly fourfold, although the impact of this on clinically relevant patient outcomes is unclear. Adherence to the treatment protocol was similar in both paracetamol and placebo groups, and there was also no difference in the use of rescue medication. Overall, our results are based on “high quality” evidence (GRADE), and therefore further research is unlikely to change this evidence. This systematic review should inform clinical practice and policy with regard to first line care of these patients.

Strengths and weaknesses of the study
This systematic review was prospectively registered, and we followed the protocol thoroughly. We included only placebo controlled trials in the review as they provide the best evidence on the efficacy of pharmacological treatment.22 We included 13 randomised trials, 10 in people with hip or knee osteoarthritis, and three investigating people with low back pain. We included two more trials than the last meta-analysis investigating people with osteoarthritis,14 and three more than the last review on people with spinal pain.21 To facilitate the

interpretation of our results, we provide precise estimates and clinically interpretable scores on 0–100 point scales of pain and disability. Overall, the quality of evidence for our outcomes considered critical for clinical decision making was ranked “high” according to the GRADE system. Moreover, this is the first review to report evidence of changes in hepatic enzyme activity associated with paracetamol, patient adherence, and use of rescue medication in patients with osteoarthritis and spinal pain. Other strengths of our review included lack of restrictions to publication language or date and use of hand search of clinical trial registries (for example, ClinicalTrials.gov) and relevant websites for unpublished trials.

The number of studies in each meta-analysis was relatively small because of small number of trials available on this topic (paracetamol versus placebo for spinal pain and osteoarthritis). For instance, in the meta-analyses investigating the efficacy of paracetamol on pain reduction for back pain we have

included a maximum number of two trials, and for osteoarthritis we included a maximum number of seven trials in a meta-analysis. Moreover, none of the trials reported data for long term follow-up, and our results are limited to the immediate and short term efficacy of paracetamol. Although we included three trials investigating spinal pain, none of these trials included patients with neck pain. In addition, one of the included trials did not report results for the placebo group, and attempts to gain access to these data were unsuccessful. Most of the included trials used the maximum dose of 4000 mg/day recommended by the US Food and Drug Administration: seven trials used 4000 mg/day as the maximum dose, two trials used 3990 mg as the maximum dose, and two trials used 3900 mg as the maximum dose. Only two trials used 3000 mg/day as the maximum dose.

Strengths and weaknesses in relation to other studies

Previous meta-analyses have concluded that paracetamol significantly reduces pain in people with hip or knee osteoarthritis.13–15 One of these reviews reported no difference in toxicity, defined by the number of patients reporting any adverse event.16 All endorsed the use of paracetamol for pain reduction in such patients. Our review included two trials not previously identified in the most recent previous meta-analysis, and our results show only a small clinically irrelevant benefit of paracetamol for pain and disability at short term follow-up.

Supratherapeutic doses of paracetamol can overwhelm the normal metabolic pathways and protective mechanisms in the liver and produce dangerous amounts of a toxic metabolite, N-acetyl-p-benzoquinoneimine.57 Most commonly this is seen in intentional overdoses, and the consequence can be liver failure. However, the drug has been used extensively for decades for chronic musculoskeletal conditions, and there is scant evidence for clinically significant toxicity with regular doses of up to 4000 mg/day in otherwise healthy adults, although some researchers contest this.27 The significant effect on hepatic enzymes that we show is well known,28 but a link with clinically important toxicity is still uncertain.

Implications for clinicians and policymakers

Interventions such as drugs that aim to provide symptomatic relief have been associated with improvement of physical function in people with osteoarthritis.59,60 Similarly, there is a high correlation of changes in pain scores and function scores in people with low back pain.61 This evidence supports the use of drugs for pain relief to improve function in these conditions, and, overall, we have shown consistent results across pain and disability outcome measures. We found that paracetamol is ineffective on both pain and disability outcomes for low back pain in the immediate and short term and is not clinically superior to placebo on both pain and disability outcomes for osteoarthritis.

Although thresholds for clinically important differences between groups are unknown for osteoarthritis, a recent study has used a minimal clinically important difference of 0.9 on a 0–10 scale (or 9 on a 0 to 100 scale) based on the median difference found in previous large trials including patients with osteoarthritis.22 Our largest observed effect size of ~3.7 points on a 0–100 pain scale, favouring paracetamol, is unlikely to be considered clinically important by patients or clinicians. Moreover, the lower boundary of the 95% confidence interval of this effect size was −5.5 and still did not reach the minimal clinically important difference of −9 defined in this review. Our results therefore provide an argument to reconsider the endorsement of paracetamol in clinical practice guidelines for low back pain and hip or knee osteoarthritis.

Recent evidence on lower limb osteoarthritis shows that exercises (such as strengthening exercise) compared with no exercise control result in large treatment effects for pain reduction (mean difference ~2.3, 95% confidence interval −2.8 to −1.26; on a 10 cm visual analogue scale).54 This effect size is much larger than the largest effect size from our pooled analyses on short term effects of paracetamol for hip or knee osteoarthritis. Paracetamol alone therefore might not be sufficient to treat hip or knee osteoarthritis and might need to be accompanied by other management strategies, such as exercises and advice/education. Future trials, however, are needed to assess the combined effect of these interventions in patients with osteoarthritis.

Unanswered questions and future research

This systematic review shows precise and clinically interpretable estimates of the size of the effect of paracetamol compared with placebo in the management of spinal pain and osteoarthritis of the hip or knee. Although our results provide “high quality” evidence that paracetamol does not provide a clinically important effect in the short term, the long term effect of this drug in the treatment of spinal pain and osteoarthritis remains unknown. Moreover, we found higher risk of abnormal results on liver function tests in patients taking paracetamol, though the clinical implications of this are uncertain. The effects of paracetamol for neck pain are unknown as we found no trials including participants with this condition.

Contributors: GCM, MLF, CGM, PHF, C-WCL, ROD, and AJMcl were involved in the conception and design of the review. GCM, MLF, and MBP developed the search strategy and performed study selection. GCM and MBP extracted data from included studies. GCM and MLF were involved in the data analysis. GCM, MLF, CGM, PHF, C-WCL, ROD, and AJMcl were involved in the interpretation and discussion of results. GCM drafted the manuscript, and MLF, CGM, and PHF contributed to the drafting of the review. CCL, ROD, MBP, and AJMcl revised it critically for important intellectual content. All authors approved the final version of the article. All authors had access to all of the data in the study and can take responsibility for the integrity of the data and the accuracy of the data analysis. MLF is guarantor.
