Regular Article - Theoretical Physics

Abstract Recently a novel hadronic state of mass 6.9 GeV, that decays mainly to a pair of charmonia, was observed in LHCb. The data also reveals a broader structure centered around 6490 MeV and suggests another unconfirmed resonance centered at around 7240 MeV, very near to the threshold of two doubly charmed $\Xi_{cc}$ baryons. We argue in this note that these exotic hadrons are genuine tetraquarks and not molecules of charmonia. It is conjectured that they are $V$-baryonium, namely, have an inner structure of a baryonic vertex with a $cc$ diquark attached to it, which is connected by a string to an anti-baryonic vertex with a $\bar{c}\bar{c}$ anti-diquark. We examine these states as the analogs of the $V$-baryonium states $\Psi(4360)$ and $Y(4630)/\Psi(4660)$ which are charmonium-like tetraquarks. One way to test these claims is by searching for a significant decay of the state at 7.2 GeV into $\Xi_{cc}\Xi_{cc}$. Such a decay would be the analog of the decay of the state $Y(4630)$ into $\Lambda_c\bar{\Lambda}_c$. We further argue that there should be trajectories of both orbital and radial excited states of the $X(6900)$. We predict their masses. It is possible that a few of these states have already been seen by LHCb.

1 Introduction

Recently, LHCb reported the discovery of a new structure in the $J/\Psi$ pair mass spectrum at around 6.9 GeV \cite{1}. This is a new exotic candidate, $X(6900)$, which is expected to be a fully charm tetraquark, that is have the quark content $cc\bar{c}\bar{c}$. Its measured mass and width are (in MeV)

$$M[X(6900)] = 6905 \pm 11 \pm 7$$
$$\Gamma[X(6900)] = 80 \pm 19 \pm 33$$

\textsuperscript{1} In holography hadrons are described by stringy configurations in curved ten dimensional curved background. The HISH model is based on a map between these strings and strings in flat four dimensional space, which are used to describe mesons, baryons, glueballs and exotics. For a holographic model of tetraquarks in a different approach see \cite{4,5}.

$$or, using a second fitting model$$

$$M[X(6900)] = 6886 \pm 11 \pm 11$$
$$\Gamma[X(6900)] = 168 \pm 33 \pm 69$$

The data also reveals a broader structure centered around 6490 MeV, referred to as a “threshold enhancement” in \cite{1}, and also suggests the existence of another resonance centered at around 7240 MeV, very near to the threshold of two doubly charmed $\Xi_{cc}$ baryons. See Fig. 1. The higher state, which we will refer to as $X(7200)$, has not been confirmed at this stage.

In describing exotic hadrons one broadly distinguishes between “molecules” which are bound states of color singlets, and genuine exotic hadrons which cannot be described in that way. In the case of the latter there should be a mechanism of building up the exotic hadron from its constituents.

In \cite{2} it was shown that the spectra of mesons and baryons of both light and heavy quark content match very nicely the spectra of the HISH (Holography inspired stringy hadron) model \cite{3}. A meson in HISH is a string with two massive particles (quarks) on its ends. A baryon of this model is built from a baryonic vertex (BV)\textsuperscript{2} which is connected to three quarks. For many states in the spectrum the preferred configuration is such that the BV and two of the quarks are close together and form a diquark, which is attached by a string to the third quark. The BV is the holographic realization of the string junction of QCD, which was proposed in \cite{7,8}.

Since the strings have an orientation, it can be used to define anti-quarks and anti-BV branes. With these basic ingredients of baryonic vertices, diquarks and strings, it is

\textsuperscript{2} In holography the BV is a $D_p$-brane wrapped over an $p$-cycle which by conservation of charge must be connected to $N_c$ strings \cite{6}.
easy to construct a tetraquark. The basic picture is of a diquark connected by a string to an anti-diquark. Holographically it involves a baryonic vertex and an anti-BV that are connected by a string. Then, since the vertices need to have in total three strings incoming or outgoing, they are each connected to two more strings, which form the diquark and anti-diquark. The meson, baryon, and tetraquark are depicted in Fig. 2. We refer to this type of tetraquark as $V$-baryonium since it can be viewed as a bound state of a BV plus diquark and an anti-BV plus anti-diquark, and the BV and anti-BV can be thought of carrying baryon number $+1$ and $-1$ respectively. Note that it is not a baryonium in the sense of a bound state of color singlets.

The $V$-baryonium tetraquarks are characterized by the following properties:

1. Since it is built from a string, then like all other stringy hadrons it must have trajectories of higher excited states, one of states with higher angular momentum, and one of higher radial excitation number. We refer to this trajectory as a HISH modified Regge trajectory (HMRT) [2]. Since the mesons, baryons, and $V$-baryonium tetraquarks can all be seen as a single string with massive particles on it, as depicted in Fig. 2, the function describing the trajectories is the same for the different types of hadrons.

2. The ground state, and possibly a few lower excited states of the $V$-baryonium, has a mass which is lower than the sum of masses of the lightest baryon and anti-baryon pair with the same diquark and anti-diquark content as that of the tetraquark. On the other hand higher excited states on its trajectory will have a mass larger than that threshold mass.

3. Correspondingly, there are different decay modes for the below and above threshold excited states. The most probable mechanism of decay of the higher excited states is via a breaking of the string the connects the BV and anti-

4. States with masses below the threshold cannot decay by a breaking apart of the string. Instead we propose here another mechanism where due to quantum fluctuations the BV and anti-BV reach the same point and annihilate. The strings attached to them are then reconnected to form two mesons with the same quark content as the original tetraquark. In QCD terms the quarks simply rearrange and separate into two mesons. The probability of the vertices meeting is suppressed exponentially in the string length squared.

Our prototype case was the exotic hadron $Y(4630)$ discovered in Belle [10] and seen to decay to $\Lambda_c\Lambda_c$. In [9] we argued that it is a charmonium-like tetraquark built from a diquark of $c$ and $u/d$, and an anti-diquark of $\bar{c}$ and $\bar{u}/\bar{d}$. Naturally, one can build many other types tetraquarks from other diquarks and anti-diquarks. In [9] we discussed the analogous bottomonium-like tetraquarks, as well as the possibility of a tetraquark containing $s\bar{s}$.

In this note we revisit the charmonium-like $V$-baryonium candidate, and apply the lessons learned from it is to the
system of the newly discovered state X(6900) and the other resonances in its vicinity. We can use the string model to predict the masses and evaluate the widths of the states.

In particular we show that there is good reason to believe that the state \( Y(4630) \) is the first radial excitation of \( \Psi(4360) \), which was seen in the \( \Psi(2S) \pi^+ \pi^- \) channel. Another resonance seen in that channel is \( \Psi(4660) \), which we identify with the \( Y(4630) \) observed in \( \Lambda_c \overline{\Lambda}_c \). The \( Y(4630) \) is above the baryon–antibaryon threshold by about 60 MeV and has both types of decays described above. The two states are both \( V \)-\( baryonium \) tetraquarks and belong on a HMRT together.

Similarly, we see that one can organize the three resonances at 6490, 6900, and 7240 MeV of Fig. 1 on a HMRT, and we can estimate their widths based on the stringy model.

We also conjecture the existence of many more \( V \)-\( baryonium \) states grouped into symmetric, semi-symmetric and asymmetric tetraquarks, which should be located around the corresponding baryon–antibaryon thresholds. We further argue that finding certain such tetraquarks can be an indirect way to observe for the first time baryons like those with bottom and charm quarks or doubly bottom baryons.

The note is organized as follows: in Sect. 2 we briefly describe the structure and properties of the \( V \)-\( baryonium \) tetraquarks in the HISH model. In Sect. 2.1 we describe the classes of tetraquarks. In Sect. 3 we describe the two possible decay mechanisms for the \( V \)-\( baryonium \) states. Section 4 is devoted to the analysis of the system of \( \Psi(4360)/Y(4630) \), the charmonium-like tetraquark candidates. In Sect. 5 we present our analysis and conjectures regarding the recently discovered state \( X(6900) \) and the other states in its vicinity. The structure and masses are described in Sect. 5.1, and decay widths in 5.2. In Sect. 6 we present some predictions about novel \( V \)-\( baryonium \) tetraquarks. In 7 we summarize our predictions and list several open questions.

2 The structure and properties of the \( V \)-\( baryonium \) tetraquarks

The construction of the HISH tetraquarks is based on the observation that many baryons in nature, and especially the excited ones, have the structure of a diquark connected by a string to a quark [11]. In holography this is realized as a baryonic vertex (BV) connected to three strings representing quarks. Two strings are very short and together with the BV form a diquark, and the last string is a long one connecting to the remaining quark.\(^3\) This system depicted in Fig. 2b. With this picture of the baryon it is natural to construct an exotic tetraquark. One can simply replace the quark at the end of the string with an anti-diquark, as depicted in Fig. 2c. Thus, a \( V \)-\( baryonium \) tetraquark is a string where on one end of it there is a BV plus a diquark and on the other end an anti-BV and an anti-diquark. The \( V \)-\( baryonium \) has “hidden baryon number” – its baryon number is zero but it is constructed from objects carrying baryon numbers +1 and −1.

In the HISH model we depict the hadron as a string with tension \( T \) and with massive endpoints \( m_1 \) and \( m_2 \). In [12] classical solutions of rotating strings with massive endpoints were written down. The corresponding energy and angular momentum of this classical system are given by

\[
M = \sum_{i=1,2} \left( \gamma_i m_i + T \ell_i \arcsin \frac{\beta_i}{\ell_i} \right),
\]

\[
J = \sum_{i=1,2} \gamma_i m_i \beta_i \ell_i + \frac{1}{2} T \ell_i^2 \left[ \arcsin \beta_i - \beta_i \sqrt{1 - \beta_i^2} \right],
\]

where \( \beta_i \) is the velocity of the endpoint, \( \gamma_i = (1 - \beta_i^2)^{-1/2} \), and \( \ell_i \) is the radius of rotation of the endpoint. The total length of the string is \( L = \ell_1 + \ell_2 \), and the solution has to obey the equations

\[
T \gamma_i = \frac{m_i \gamma_i \beta_i^2}{\ell_i}
\]

for \( i = 1, 2 \), which are the force equations on the endpoint particles. The endpoint velocities \( \beta_i \) are related to each other from the condition that the angular velocity is the same for both endpoints, implying

\[
\omega = \frac{\beta_1}{\ell_1} = \frac{\beta_2}{\ell_2}.
\]

These are the defining equations of a function \( J(M) \), which we call the classical HMRT (holography modified Regge trajectory). For the case of massless endpoints this reduces to the famous classical Regge trajectory relation \( J = \alpha' M^2 \) with the Regge slope \( \alpha' = (2\pi T)^{-1} \). Note that we typically associate \( J \) with the orbital angular momentum of a state, the spin of the endpoints being added separately. We reserve the notation \( L \) for the string length.

By comparing the predictions of the HISH model (including quantum corrections) with the known spectra of mesons and baryons the optimal values of the “string endpoint masses” \( m_{q_1 q_2} \) for the quarks and for the diquarks of the various flavored quarks were determined [2]. We assume here, based on our previous analysis of the baryonic spectra, that the mass of a diquark is given at leading order by \( m_{q_1 q_2} = m_{q_1} + m_{q_2} \), even though in the holographic picture this is far from obvious due to the BV being part of the diquark.

\(^3\) In holography, for a diquark that includes a heavy flavor quark, the string that connects it to the BV is a long string in the holographic direction but its projection to real space coordinates is small.

\(^4\) The string endpoint mass corresponds in holography to the action of the string along the vertical segment of the hadronic string. The mass is roughly the tension times the length of the string in the holographic direction.
The previous expressions are classical. Quantizing the fluctuations of the string around the classical solution yields for the case of the massless endpoints the quantum Regge trajectory \( J + n = \alpha' M^2 + a \) where \( \omega_n = n \) is the eigenfrequency of the \( n \)-th excited state and \( a = \frac{1}{2} \sum_n \omega_n \) is referred to as the intercept. In [13] the quantization of the string with small massive endpoints was performed in the non-critical dimensions \( d = 4 \) and the eigenfrequencies and intercept were determined as a function of the endpoint masses.

For phenomenological purposes we found [2, 14] that we should introduce the quantum corrections by the replacement \( J \rightarrow J + n - a \), in analogous fashion to the massless string. Since we add \( n \) and not \( \omega_n \) (which is only known for fluctuations around strings obeying \( TL/m \gg 1 \)), the price we pay is that we get different effective slopes for orbital and radial trajectories, \( \alpha' \neq \alpha'' \). As for the intercept, in bosonic string theory \( a = 1 \), which implies a tachyonic ground state. To fit the experimental data one always needs a negative intercept. Since we define it in relation to the orbital angular momentum, we can write \( \tilde{a} = a - S < 0 \), where \( S \) is the spin (not the total angular momentum) of the system and \( a \) the intercept defined with respect to the trajectory of the total angular momentum as a function of the mass. The negative intercept implies that effectively there is a repulsive Casimir force that acts on the string endpoints, \( F_C = \frac{-\tilde{a}}{L^2} \) where \( L \) is the length of the string. Due to this force non-rotating strings, that classically would collapse to zero size because of the string tension, now have a finite length and are non-tachyonic.

When comparing the intercepts of mesons and baryons we find that they are different even when they are composed of the same type of quarks. This implies that the fluctuations of a system that includes a string and an endpoint built from a BV and a diquark is different from that with an ordinary quark as an endpoint. There are two possible reasons for this difference: (i) the quantum fluctuations of the BV, and/or (ii) a change of the boundary condition of the string which changes the eigenmodes of the fluctuations. If we denote by \( \tilde{a}_m \) and \( \tilde{a}_b \) the intercepts of a meson and a baryon of the same flavor structure, then the difference of the intercepts is \( \Delta \tilde{a} = \tilde{a}_b - \tilde{a}_m \). If the cause of the difference is the quantum fluctuations of the BV then we anticipate that \( \tilde{a}_l \equiv \tilde{a}_m + 2 \Delta \tilde{a} = \tilde{a}_b + \Delta \tilde{a} \). In this work we simply use experimental data to determine the intercepts when necessary.

The parity and charge conjugation parity of the \( V \)-baryonium should depend on the string and its endpoints. For mesons the rules \( P = (-1)^{L+1}, C = (-1)^{L+S} \), which are based only on the endpoint quarks, are very well known. Constructing tetraquarks as a bound state of a diquark and an anti-diquark, then unlike for mesons the endpoints will be bosons of spin 0 or 1. Thus, now parity and charge conjugation should be \( P = (-1)^L \) and \( C = (-1)^{L+S} \).

2.1 Classes of tetraquarks

As was discussed in [9] tetraquark configurations can be classified according to symmetries in their flavor content. We group them into symmetric, semi-symmetric and asymmetric states as follows:

- **Symmetric tetraquarks** where the anti-diquark is built from the anti-quarks associated with those found in the diquark. For instance the diquark \( cu \), and the anti-diquark \( \bar{c}\bar{u} \). These symmetric tetraquark configurations are flavorless and carry zero electric charge. Altogether there are 15 different symmetric tetraquarks for 15 unique types of diquarks composed of quarks of five flavors.

- **Semi-symmetric tetraquarks** in which there is one pair of quark and antiquark of the same flavor and one pair which includes a quark and an anti-quark of different flavors, for instance \( (cu)(\bar{c}\bar{s}) \). Thus the flavor content of these exotic hadrons is the same as of mesons that carry non-trivial flavor and they can carry a charge of \( +1, 0 \), or \( +1 \). We have 5 possibilities for a matched pair and 20 for the unmatched pair, so altogether there are 100 possible semi-symmetric tetraquarks.

- **Asymmetric tetraquarks**, where both pairs are of different flavor. We could have any pair of quark forming the diquark and any two antiquarks forming the anti-diquarks thus altogether there are a priori \( 15 \times 15 = 225 \) possibilities of tetraquarks. Out of the 225 tetraquarks, we have 15 that are symmetric, 100 semi-symmetric, and thus 110 are asymmetric ones. The asymmetric tetraquarks can carry a charge of \( -2, -1, 0, +1, \) or \( +2 \), with a charge of \( \pm 2 \) being an obviously exotic feature (for hadrons with baryon number zero). These can be manifestly exotic due to flavor content as well, e.g. \( (cs)(\bar{u}\bar{d}) \) for which a candidate was recently observed [15–17].

3 Decays of the \( V \)-baryonium tetraquarks

The generic decay of a stringy hadron is by breaking up of the string into two strings. However, for mesons we know that there are also decay channels that involve an annihilation of the string endpoints, as is the case for OZI suppressed decays for the low lying charmonium and bottomonium mesons [14].

The decay of the low lying tetraquark states cannot be via breaking of the string since they can generally be below the relevant threshold. Their decays involve an annihilation, not of a quark–antiquark pair, but rather of the BV with the anti-BV.

The higher excited states on the \( V \)-baryonium HMRT can break apart, and above threshold those are the dominant decays. We describe both types of decays in the following.
3.1 The decay mechanism of below threshold states

As explained in the introduction the natural decay mode of the $V$-baryonium tetraquark is into a baryon and anti-baryon. However, this cannot take place for the ground state and possibly other low lying states because their mass is less than that of the baryon anti-baryon pair. This is expected to be a generic property of the $V$-baryonium since it can be viewed as a type of baryon anti-baryon bound state, but where one pair of a quark and anti-quark was annihilated, making it a state of four constituents and not six. Then there is a certain binding energy which can ascribed to these states and therefore they cannot decay into a the baryon anti-baryon pair. However, the $V$-baryonium states are not stable since they can decay via other channels. A possible decay mechanism involves the annihilation of the BV with the anti-BV. Due to quantum fluctuations there is a certain probability that the BV and anti-BV, that on the average are separated at a distance $L$ (the length of the string), will hit each other. The annihilation process should be accompanied by a reconnection of the strings that originally connected the BV to the quarks on flavor branes with the strings that stretched from the anti-BV to the flavor branes but at another point in space. This mechanism of decay is depicted in Fig. 3a. In QCD terms the quarks have simply reorganized to form two mesons.

The probability of such a decay is the product of the probability that the BV and anti-BV will be at the same point in space times the probability of an annihilation of the BV pair.

$$P = P_{\text{same location}} \times P_{\text{annihilation}}$$

(3.1)

In [14] we estimated $P_{\text{same location}}$ for a similar system to be

$$P_{\text{same location}} = \sqrt{\frac{\pi}{2T}} e^{-\frac{L^2}{T}} \approx \sqrt{\frac{\pi}{2T}} e^{-\frac{4m^2}{M^2}}$$

(3.2)

where $T$ is the string tension, $M$ is the mass of the tetraquark and $m$ is the mass of the BV and diquark. The main result is the exponential suppression in the string length.

In the simplest process of reconnection of the strings following the annihilation, the decay products are two mesons with the same quark content as the original tetraquark. There are also processes where additional light $q\bar{q}$ pairs are created and there are three or more mesons in the final state. An example is the decay of the charmonium-like $V$-baryonium candidate $\Psi(4360)$ into $\Psi(2S)\pi^+\pi^-$ which we examine in Sect. 4. In that case we still expect the overall factor of $P_{\text{annihilation}} \sim e^{-TL^2/2}$ in the decay width.

3.2 The decay mechanism of the higher excited states

For $V$-baryonium states with masses above the baryon–antibaryon threshold then the natural mode decay is via the breakup of the string. This is drawn in Fig. 3b. As was shown in [14], the total decay width of any hadron that involves a breaking up of a string is given by

$$\Gamma = \frac{\pi}{2} A \times \Phi \times TL$$

(3.3)

Where $A$ is a dimensionless constant found to be $A \sim 0.1$ for mesons, $T$ and $L$ are the string tension and length. The factor $\Phi$ accounts for phase space. As in the previous subsection, here also we can express the string length $L$ in term of the mass of the tetraquarks and the masses of the string endpoint particles. The linearity of the decay width in $L$ can be intuitively understood since the string can be torn apart at any point along its length.

The phase space factor $\Phi$ takes the form

$$\Phi = \frac{2|p_f|}{M}$$

$$= \sqrt{\left(1 - \frac{M_1 + M_2}{M}\right)^2 \left(1 - \frac{M_1 - M_2}{M}\right)^2}$$

(3.4)

where $M$ is the mass of the decaying particle, and $M_1$ and $M_2$ the masses of the outgoing particles, in the main channel.
of decay. It is only included in the phenomenological model to account for the suppression of decays for states that have little phase space to decay, so it is only relevant to states just above threshold to decay, and should not be included for states which have multiple viable decay channels (see section 8.1.2. in [14] for a detailed explanation).

Lastly, we discuss the possibility that both types of decays discussed in this section are present. The simplest way to account for both is to add the two widths as

$$\Gamma = \frac{\pi}{2} A \times \Phi \times TL + A \sqrt{T} \times e^{-\frac{T}{T_c^2}}$$

(3.5)

where $A$ is another dimensionless constant, proportional to $P_{\text{annihilation}}$ from the previous section. The former channel will be dominant for excited states, which are long strings, but could be suppressed by the phase space factor for near-threshold states.

4 The $\Psi(4360)$ and $Y(4630)$ tetraquark system

The sector of hidden charm mesons is particularly rich in exotic candidates [18–20]. The prototype state that we believe is a $V$-baryonium state is the $Y(4630)$ which was observed by Belle in 2008, in the process $e^+e^- \rightarrow \gamma \Lambda_c^+\Lambda_c^-$, with a significance of 8$\sigma$ [10]. The parameters measured there for the $Y(4630)$ were

$$J^{PC} = 1^{--}, \quad M_{Y(4630)} = 4634^{+9}_{-11} \text{,}$$

$$\Gamma_{Y(4630)} = 92^{+41}_{-32} \text{.}$$

(4.1)

In [9] we considered several options of interpretation of this hadronic state and concluded that the most plausible possibility is that it is a $V$-baryonium tetraquark. This conclusion is largely based on the fact that it decays to $\Lambda_c\overline{\Lambda}_c$ which as mentioned above is the natural decay mode of such a state. The tetraquark nature of the $Y(4630)$ state was explored in other contexts as well [21–25].

The $Y(4630)$ is often identified, including by the PDG [26], with the nearby resonance $\Psi(4660)$ (formerly $Y(4660)$), which was seen in $e^+e^- \rightarrow \gamma \pi^+\pi^-\Psi(2S)$. It also has $J^{PC} = 1^{--}$, and its mass and width are, according to the latest average by the PDG [27],

$$M_{\Psi(4660)} = 4633 \pm 7 \text{,} \quad \Gamma_{\Psi(4660)} = 64 \pm 9 \text{ (4.2)}$$

Note that these averages also include the $Y(4630)$ measurements of Belle.

We have two options. Either there are two separate states and the $Y(4630)$ decays predominantly to baryon–antibaryon, or they are the same state that has both decays to $\Psi(2S)\pi^+\pi^-$ and $\Lambda_c\overline{\Lambda}_c$. In the following we expand upon the discussion in [9] to include the latter possibility. Since the $Y(4630)$ is only about 60 MeV above the $\Lambda_c\overline{\Lambda}_c$ threshold, it is more likely that it should have both channels of decay for its width to be as large as measured, as we show below. There have been multiple works studying the $Y(4630)$ and $\Psi(4660)$. These include [28–38].

Another role is played by the $\Psi(4360)$, a lower mass state which has very similar properties. It is another $1^{--}$ state seen in $e^+e^- \rightarrow \gamma \pi^+\pi^-\Psi(2S)$. Its mass and width are measured to be

$$M_{\Psi(4360)} = 4368 \pm 13 \text{ MeV} \text{,}$$

$$\Gamma_{\Psi(4360)} = 96 \pm 7 \text{ MeV} \text{ (4.3)}$$

This state is well below the $\Lambda_c\overline{\Lambda}_c$ threshold, but it is as wide or wider than the $Y(4630)$.

The basic proposition of [9] was that if the $Y(4630)$ is a $V$-baryonium tetraquark, it should be part of a HMRT. Using the values of $m_{\text{ct}} \approx m_c$ and $\alpha'$ of the $c\overline{c}$ trajectories, we used the known mass of the state $Y(4630)$ to extrapolate from it to higher states along the trajectory. We use the values

$$m_c = 1490 \text{ MeV} \text{,} \quad \alpha_f' = 0.86 \text{ GeV}^{-2} \text{,}$$

$$\alpha_n' = 0.59 \text{ GeV}^{-2} \text{.}$$

(4.4)

There are two different slopes, determined from the analysis of the charmonium spectrum: one for orbital trajectories in $J$ and one for radial trajectories in $n$.

By extrapolating the trajectory backwards to lower masses, we find that the $\Psi(4360)$ is exactly at the right mass for the $Y(4630)$ to be its first radially excited state.

We now suggest that $Y(4630)$ and $\Psi(4660)$ are the same state, which is a radially excited partner of the $\Psi(4360)$, and the two states are both $V$-baryonium tetraquarks. The $\Psi(4360)$ is below threshold and decays via BV-anti-BV annihilation as described in Sect. 3.1, while the $Y(4630)$ which is above but close to the $\Lambda_c\overline{\Lambda}_c$ threshold has both types of decays.

For the higher excited states, the $\Lambda_c\overline{\Lambda}_c$ decays should be dominant, and their masses should be such that they fall on the HMRT.

We can estimate the two partial decay widths of the $Y(4630)$ in the following way. The decay via a breakup of the string is given by Eq. 3.3. Writing it for $Y(4630)$,

$$\Gamma_{\text{tear}} = \frac{\pi}{2} A \times \Phi(Y(4630) \rightarrow \Lambda_c\overline{\Lambda}_c) \times TL \big|_{Y(4630)}$$

$$= A \times (268 \text{ MeV}) \lesssim 27 \text{ MeV}$$

(4.5)

In the last step we use the typical value of $A$ that we obtain from meson fits, which is around 0.1 or less.\footnote{There is an ambiguity in this calculation since we have two choices we can make for the tension $T = (2\pi\alpha')^{-1}$, corresponding to the two measured slopes. Since we take $Y(4630)$ to be a radially excited state we use $\alpha_n'$ in the calculation.}

This is not compatible with the full width of $Y(4630)$ as measured by Belle. We can evaluate the partial width for $\Psi(4360)$ based on the width of the $\Psi(4630)$ as
include of the phase space factor for higher states, we write defining the tension and in the question of whether or not to states on the trajectory. However, given the ambiguities in the pair excited states are expected to

There is a candidate for the latter state, which is \( \chi \) assigned to the mass of \( 4500 \) MeV with a width of \( 92 \pm 29 \) MeV. This matches with the prediction in Table 2.

\[ \Gamma_{\text{annihilation}} = \Gamma[\Psi(4360)] \times \frac{\exp(-\frac{T L_1^2}{2})}{\exp(-\frac{T L_2^2}{2})}[\Psi(4360)] \approx 0.50 \times \Gamma[\Psi(4360)] \approx 48 \text{ MeV} \quad (4.6) \]

Now we can see that adding both channels as in Eq. 3.5 gives a result that is close to the width of the \( \Psi(4660) \), which is measured at \( 64 \pm 9 \). By taking \( A \) to be \( \approx 0.06 \) we get close to the exact measurement.\(^6\)

In Tables 1 and 2 we write the predicted masses of states on the radial and orbital HMRTs of the \( \Psi(4360) \) and \( \Psi(4660) \). We can also use Eq. 3.5 with \( A \) and \( \tilde{A} \) as determined from the pair \( \Psi(4360)/\Psi(4660) \) to calculate the width of the other states on the trajectory. However, given the ambiguities in defining the tension and in the question of whether or not to include of the phase space factor for higher states,\(^7\) we write only estimates. Unlike in [9] we now use the two states rather than only \( Y(4360) \) as input. If we measure the slope between \( \Psi(4360) \) and \( \Psi(4660) \) we get \( \alpha'_c = 0.60 \text{ GeV}^{-2} \), exactly as for the charmonium trajectories.

The next state \( 1^{--} \) should be just below \( 4900 \) MeV and decay predominantly to \( \Lambda_c \bar{\Lambda}_c \). We estimate the ratio \( \Gamma_{\text{leak}}/\Gamma_{\text{annihilation}} \) for it to be roughly between 3 and 6.

The \( \Psi(4360) \) and \( \Psi(4660) \) could also have a scalar state below them on their respective orbital HMRTs, with \( J^{PC} = 0^{++} \). These states are calculated to be at \( 4170 \) and \( 4460 \) MeV. There is a candidate for the latter state, which is \( \chi_c(4500) \) (also known as \( X(4500) \)). This state was seen in the \( J/\Psi \phi \) channel, and it is an exotic candidate of mass \( 4506.9_{-19}^{+16} \) MeV and width \( 92 \pm 29 \) MeV. This matches with the prediction in Table 2.

### Table 1 States on the radial trajectory of the \( \Psi(4360)/\Psi(4660) \)

| \( n \) | Mass    | Width  |
|------|---------|--------|
| “-1” | \( 4070 \) | 160–200 |
| 0    | \( 4368 \pm 13 \) | \( 96 \pm 7 \) |
| 1    | \( 4633 \pm 6 \) | \( 64 \pm 9 \) |
| 2    | \( 4870 \) | 80–210 |
| 3    | \( 5100 \) | 100–220 |
| 4    | \( 5300 \) | 120–240 |

### Table 2 Orbital trajectories of the \( \Psi(4360) \) and \( \Psi(4660) \)

| \( J^{PC} \) | Mass    | Width  | \( J^{PC} \) | Mass    | Width  |
|-------------|---------|--------|-------------|---------|--------|
| 0^{++}      | \( 4170 \) | 160–200 | 0^{++}      | \( 4460 \) | 70–100 |
| 1^{--}      | \( 4368 \pm 13 \) | \( 96 \pm 7 \) | 1^{--}      | \( 4633 \pm 6 \) | \( 64 \pm 9 \) |
| 2^{++}      | \( 4550 \) | 50–80  | 2^{++}      | \( 4800 \) | 90–210 |
| 3^{--}      | \( 4720 \) | 70–170 | 3^{--}      | \( 4960 \) | 100–230 |
| 4^{++}      | \( 4880 \) | 80–210 | 4^{++}      | \( 5110 \) | 120–240 |

### 5 Analyzing the \( X(6900) \) and \( X(7200) \) exotic hadron states

We use the \( \Psi(4360)/Y(4630) \) system just described as our guiding line for the analysis of the newly discovered \( X(6900) \) and the unconfirmed state near \( 7.2 \) GeV, which we call \( X(7200) \). We also address the wider state near \( 6490 \) MeV.

We compute the states’ masses based on an assignment to a modified Regge trajectory, and evaluate their widths within the HISH model.

### 5.1 The structure and masses

We explore the system assuming it is a heavier analogue of the \( \Psi(4360)/Y(4630) \) system described in the previous section. The basic assumption is that it is a fully charmed \( V-baryonium \) tetraquark, with the quark content \( cc\bar{c}\bar{c} \), which is built as a string connecting a diquark to an anti-diquark. The tetraquark made up of four heavy quarks has been an object of theoretical study for some decades [39–48]. Many of the models in the literature describe the tetraquark as a diquark–antidiquark bound state [39,40,42–45,47,48], although other possibilities exist. In the holographic realization this configuration involves a BV and an anti-BV.

In the HISH model the states are described by a string with massive particles on its endpoints, connecting a diquark to an anti-diquark of the same mass.

The experimental data are taken from [1]. There, only the mass of \( X(6900) \) is fully specified and measured. However, we can read from the fit done in their Fig. 7 where the other peaks are. There is a lower peak, wider than \( X(6900) \), centered at around \( 6490 \) MeV which is dubbed a threshold enhancement in [1], rather than a resonance. The higher peak, the \( X(7200) \) is a Breit–Wigner resonance located around \( 7240 \) MeV. This is very near the threshold for baryon–antibaryon decay which is located at

\[ 2M_e \approx 7242.4 \pm 1.4 \text{ MeV} \quad (5.1) \]

\(^6\) Fitting the same formulas with \( T = (2\pi \alpha'_c)^{-1} \) gives \( A = 0.1 \), which is more consistent with the other trajectories fitted in [14].

\(^7\) As was explained in [14], the factor \( \Phi \) is added by hand only in those cases where there is a single allowed channel with limited phase space. For higher excited states the growth of the total width should be simply linear in the string length.
The four peaks in Fig. 7 of [1] are measured by us to be centered at 6260, 6490, 6900, and 7240 MeV. See Fig. 1.

The quantum numbers, $J^{PC}$ of the states are not confirmed by the experiment. We do not offer a prediction for the new states. Instead, we will place them on Regge trajectories such that all the states on a radial trajectory have the same $J^{PC}$, while for orbital trajectories $J$ is increasing and the $P$ and $C$ values alternate with the increasing orbital angular momentum.

5.1.1 The HISH modified Regge trajectories

The tetraquarks that are built from a BV and anti-BV all share two characteristics. The first is that, if they are heavy enough, their natural decay mode is to a baryon–antibaryon pair. The second property is that excited states, whether with higher angular momentum or with radial excitation number, should reside on HMRTs. These are based on the spectrum of the string connecting the BV and the anti-BV.

In [9] we determined the trajectories associated with tetraquarks made up of diquarks that contain one $b$, $c$, or $s$ quark and another light quark, e.g. $bq\bar{q}$ or $cq\bar{q}$, where $q$ is $u$ or $d$. The results for the charmonium-like $V$-baryonium are given above in Table 1. In a similar manner we conjecture the trajectories on which the fully charm $cc\bar{c}\bar{c}$ tetraquark resides.

The parameters which determine the HMRT of a given hadron are the endpoint masses, the string tension (equivalently the Regge slope), and the intercept.

For the $cc\bar{c}\bar{c}$ state, we take a mass of $m_{cc} = 2m_c$ for both the diquark and anti-diquark at the endpoint. The mass of the charm quark as a string endpoint was measured from the spectrum of HMRTs of charmed mesons [2,9], and is $m_c = 1490$ MeV.

The value of the Regge slope is also known, but we have found that while it is a universal parameter for light hadrons, it starts to depend on the mass when looking at $c\bar{c}$ and heavier states. Since the $X(6900)$ is in an intermediate range between $c\bar{c}$ and $bb$ we could expect the relevant slope to be somewhere between those measured for the $c\bar{c}$ and $bb$ trajectories.

We also observe a difference between the slopes of orbital and radial trajectories, which we denote by $\alpha'_f$ and $\alpha'_n$ respectively. The results of [2] are that for light mesons the slopes are

$$\alpha'_f = 0.88 \, \text{GeV}^{-2} \quad \alpha'_n = 0.80 \, \text{GeV}^{-2} \quad (5.2)$$

while for the bottomonium trajectories both are lower

$$\alpha'_f = 0.55 \, \text{GeV}^{-2} \quad \alpha'_n = 0.42 \, \text{GeV}^{-2} \quad (5.4)$$

We also have a single measurement of the radial slope coming from a pair of $B_c$ mesons, which gives $\alpha'_n = 0.56 \, \text{GeV}^{-2}$, a value between the charmonium and bottomonium values. Then we calculate the intercept for each slope, and then the higher states on the trajectory. We can also go backwards on a trajectory and find where a lower, unexcited state would be. We can go at most two steps backward before we reach masses lower than $4m_c$, so there can be at most two states preceding $X(6900)$ on the trajectory. For lower values of the slope the $n = -2$ state is not present.

We predict the first few states on the trajectory of the $X(6900)$ in Table 3. The mass of $X(6900)$ is taken to be 6895 MeV for the purpose of the calculations, being a simple average over the two measurements. Experimental uncertainties should be added to the estimates in the table.

One result that is not dependent on the slope in this range is that the $n = 1$ state around 7200 MeV is generally expected to be below or very close to the threshold of two doubly charmed baryons. This is in contrast to the $Y(4630)$, which is 60 MeV above threshold.

In fact, there appears to be good agreement between the Regge trajectory with the $bb$ slope, $\alpha''_n = 0.42 \, \text{GeV}^{-2}$, and the three states seen by LHCb. If we take as input the mass of $X(6900)$ and that value of $\alpha''_n$, then going backward on its trajectory we should find a state with mass 6470 MeV, and a higher state near 7240 MeV, which nearly exactly matches with [1]. See Fig. 4. On this trajectory the next state, which should decay predominantly to $\Xi_{cc} \tilde{\Xi}_{cc}$, would be near 7500 MeV.

5.2 Decays of the $X(6900)$ and $X(7200)$ states

As explained in Sect. 3 there are different mechanisms of decay for states below or above the baryon–antibaryon threshold, as we have argued is the case for the pair $\Psi(4360)$ and $Y(4630)$. Here we examine the states $X(6900)$ and $X(7200)$, in direct analogy to the discussion in Sect. 4.

The states below the baryon–antibaryon threshold are expected to decay in a process that involves annihilation of the BV and anti-BV, a process which is suppressed exponentially in the string length. Above threshold, they should
Table 3  Trajectories of the $X(6900)$, radial and orbital. We take values between 0.42 and 0.60 GeV$^{-2}$ for the radial trajectory slope $\alpha'_r$, while $\alpha'_b$ goes between 0.55 and 0.88 GeV$^{-2}$. The $X(6900)$ is assigned $n = 0$ and $J_{orb} = 0$, although we include the possibility that it is not the ground state by extrapolating backwards on the trajectory as well. The lower states are provisionally labeled by negative $n$ or $J_{orb}$, but in fact if they exist the lowest of them would be $n = 0$ and $J_{orb} = 0$. For lower slopes the mass differences between successive states are higher and the intercept smaller (in absolute value). The intercept is obtained to be between $-2.3$ and $-1.6$ for the radial trajectory and between $-3.4$ and $-2.1$ for the orbital one, depending on the slope. We do not predict the quantum numbers of the states. States in the left table will all have the same $J^{PC}$, while on the right $J$ is increasing with alternating $PC$, as in Table 2.

| $n$  | Mass     | $J_{orb}$ | Mass    |
|------|----------|-----------|---------|
| $"-2"$ | 6000–6220 | $"-2"$    | 6110–6480 |
| $"-1"$ | 6460–6610 | $"-1"$    | 6570–6700 |
| 0    | 6895     | 0         | 6895    |
| 1    | 7140–7230 | 1         | 7060–7160 |
| 2    | 7350–7530 | 2         | 7220–7390 |
| 3    | 7560–7800 | 3         | 7360–7610 |

Fig. 4  Radial HMRT of the $X(6900)$ with $\alpha' = \alpha'_b = 0.42$ GeV$^{-2}$. The $X(6900)$ is placed at $n = 0$ although it might not be the ground state. The resonances at 6490 MeV at 7240 MeV, placed here at $n = -1$ and 1 respectively, both fit the trajectory well. The next few states are at 7530, 7800, and 8050 MeV.

decay via tearing of the string, which is proportional to the length. States above but close to the threshold are expected to have both modes.

5.2.1  The decay of the $X(6900)$

The mechanism of the decay of the $X(6900)$ was explained in 3.1. The probability of the decay process is given in Eq. 3.2. To avoid a complicated calculation of the pair of BV anti-BV annihilation we will make the plausible assumption that it is the same for the $\Psi(4360)$ system and the $X(6900)$ and hence the ratio of the widths of the latter to the former is

$$\frac{\Gamma_X(6900)}{\Gamma_{\Psi(4360)}} \propto \exp\left(\frac{-T\ell^2}{2}|\chi(6900)\rangle\right) \exp\left(\frac{-T\ell^2}{2}|\chi(4360)\rangle\right)$$

$$\approx \exp\left(\frac{-4(M_X(6900) - 4m_c)^2}{9\ell^2}\right) \exp\left(\frac{-4(M_{\Psi(4360)} - 2(m_c + m_b))}{9\ell^2}\right)$$  (5.5)

Since it is a ratio of two exponential terms it is quite sensitive to uncertainties of the parameters and we cannot determine an accurate prediction of the width. In addition, there is no guarantee that the states share the same string tension, so we must account for that as well. By checking some plausible values of the string tension and the diquark masses, we see that the ratio is always larger than $\approx 1.9$. Since the width of $\Psi(4360)$ is $96 \pm 7$ MeV, the model suggests that

$$\Gamma[X(6900)] \gtrsim 180 \text{ MeV}$$  (5.6)

Therefore it is more compatible with the larger width of $168 \pm 33 \pm 69$ MeV for $X(6900)$.

We can also use the formula to predict the ratio of widths between $X(6900)$ and the lower state at 6490 MeV, assuming that it shares the same $V$-baryonium structure, with the result that is should be wider than $X(6900)$ by a factor of 1.4–2.0. This qualitatively matches the data, which shows that $X(6900)$ is the narrower state. Based on the lower bound above, the 6490 MeV state should have a width of at least 250 MeV.

Note that the state at 6900 MeV is heavy enough for the baryon–antibaryon decay to $J/\Psi D\bar{D}$, which would be interesting to see in experiment. This can also lower the prediction for the width of the lower state depending on the branching ratio.

5.2.2  The decay of the $X(7200)$

It is not clear whether the $X(7200)$ is heavy enough for the baryon–antibaryon decay to $\Xi_{cc} \Xi_{cc}$ to occur. The data from LHCb suggests that it is very near to the threshold, and so do our calculations of its mass as the first radially excited partner of the $X(6900)$.

If it is above threshold the natural decay mechanism, as was shown in Fig. 3, is of breaking the string and creating a quark and antiquark. The decay products are then a baryon–antibaryon pair.

We can estimate the decay width of the $X(7200)$ in two possible models. The first is assuming that it is above threshold and decays only to the baryon–antibaryon, and assuming that likewise $Y(4630)$ decays only to $\Lambda_c \bar{\Lambda}_c$. Then we can estimate that the ratio of the two states’ widths is approximately given by the ratio of their lengths, adjusted for phase space corrections:

8 We thank Ivan Polyakov for pointing this out to us.
\[
\frac{\Gamma_X(7200)}{\Gamma_Y(4630)} \simeq \frac{(TL)[X(7200)]}{(TL)[Y(4630)]} \times \frac{\Phi[X(7200) \to \Xi_{cc} \bar{\Xi}_{cc}]}{\Phi[Y(4630) \to \Lambda_c \bar{\Lambda}_c]}
\]

(5.7)

This can be written solely as a function of the mass of the \(X(7200)\), or in terms of \(\Delta M = M_X(7200) - 2M_{\Xi_{cc}}\). It is given by

\[
\frac{\Gamma_X(7200)}{\Gamma_Y(4630)} \approx 4.78\sqrt{x}(1 + 2.45x)
\]

(5.8)

where \(x = \frac{\Delta M}{M_{\Xi_{cc}}}\). We can use this simple formula to estimate the decay width. For instance, if the state is just above threshold, with \(\Delta M = 10\) MeV, then \(\Gamma_X(7200) \approx 23\) MeV.

For a larger mass difference \(\Delta M = 50\) MeV we get that \(\Gamma_X(7200) \approx 53\) MeV, and so on. Given the large error in the measured width of \(Y(4630)\) from \(\Lambda_c \bar{\Lambda}_c\) (Eq. 4.1), then these values will also have an error of about 40–50% in addition to uncertainties from the model.

The second model is more in line with what was presented in Sect. 4, and includes the decays of \(X(7200)\) by BV-anti-BV annihilation, resulting in a pair of charmonia. In the same way we calculated the width of \(\Psi(4630)\) based on the width of the below threshold \(\Psi(4360)\), we can use the \(X(6900)\) to give an estimate of \(\Gamma_X(7200)\) when \(X(7200)\) is below threshold. Then its width should be narrower than that of \(X(6900)\) as given by the ratio of \(\exp(-TL^2/2)\), as in the last section. The result is that the width of the \(X(7200)\) should be 45–70% of the width of the \(X(6900)\), depending on the state’s exact mass and the value used for the tension.

Then there is the possibility that the state is above threshold and both decay channels are present, as we argued was the case for the \(Y(4630)/\Psi(4630)\). In that case Eq. (5.8) becomes the ratio of the partial decay widths \(\Gamma_{\text{total}}[X(7200)]/\Gamma_{\text{total}}[\Psi(4630)]\).

Then the decay width is estimated as

\[
\Gamma[X(7200)] \approx (0.45-0.70) \times \Gamma[X(6900)] + 4.78\sqrt{x} \times \Gamma_{\text{total}}[\Psi(4630)]
\]

(5.9)

where \(\Gamma_{\text{total}}[\Psi(4630)]\) was about 20–30 MeV. The second term is less than 10 MeV as long as \(\Delta M \lesssim 40\) MeV, so the larger part will come from the first term, which is in the range 40–140 MeV depending on the measurement used for \(\Gamma[X(6900)]\).

6 Predictions about novel V-baryonium tetraquarks

Using the same logic, as we have used above it is natural to predict other V-baryonium states. For example an exotic tetraquark built of diquark of \(c\) and \(s\) quarks with mass \(M_{Y_{cs}} = 2M_{\Xi_{cc}} + \Delta M_{cs} = 4.936\) GeV + \(\Delta M_{cs}\), where \(\Delta M_{cs}\) is the difference between the actual mass of the hadron and the threshold mass which is sum of mass of the baryon and anti-baryon. For the case \(Y(4630)\), \(\Delta M \approx 60\) MeV.

The states conjectured to have a structure of a tetraquark - \(Y(4630)\), \(X(6900)\) and related states discussed above, and \(Y_{cs}\) just discussed are symmetric in their structure in the sense that for the quarks \(q_1, q_2\) attached to the baryonic vertex, on the other side there are \(\bar{q}_1\) and \(\bar{q}_2\) which are attached to the anti-BV.

However, as was mentioned already in [9], there is no reason not to expect also asymmetric tetraquarks, namely where on the anti-BV there will be \(\bar{q}_3\) which is different than \(\bar{q}_1\) and \(\bar{q}_2\) and similarly also for \(q_4\). For exotics that include both \(c\) and \(\bar{c}\) asymmetric tetraquarks can have the following structures \((c, c, \bar{c}, \bar{s})\), \((c, c, \bar{c}, q)\), \((s, s, \bar{c}, \bar{q})\), \((c, s, \bar{c}, \bar{q})\), where \(q = u, d\). If these exotic hadrons admit the structure described above their masses should be somewhat larger than

\[
\begin{align*}
M_{Y_{c,c,s,\bar{c}}} &\gtrsim M_{\Xi_{cc}} + M_{\Xi_{cs}} = 6089\ MeV \\
M_{Y_{c,c,q,\bar{c}}} &\gtrsim M_{\Xi_{cc}} + M_{\Lambda_c} = 5897\ MeV \\
M_{Y_{c,\bar{c},q,\bar{c}}} &\gtrsim M_{\Xi_{cs}} + M_{\Lambda_c} = 4754\ MeV
\end{align*}
\]

In [9] we have presented a detailed analysis of the analogs of the \(Y(4630)\) for the exotics build from strange and bottom quarks, namely tetraquarks where there is one bottom/strange quark attached to the BV and a single anti-quark with the same flavor to the anti-BV. In analogy to the passage from a charmonium-like to the fully charm V-baryonium there may be exotics related to such transformations also for the bottom, strange, and possibly for light-quarks of the form \(Y_q \to Y_{qq}\) where \(q\) stands for \(b, s, u/d\).

In Table 4 we list the threshold masses for all possible symmetric V-baryonium. In the first two lines, since the corresponding baryons have not be found yet, we estimated their masses instead. In all other lines we use the PDG values of the corresponding baryons.

It is trivial to determine the threshold masses for all of them. For a V-baryonium with a content of \((q_1, q_2, q_3, q_4)\) the threshold mass is the sum of the masses of the lightest baryon \((q_1, q_2, q)\) and the anti-baryon \((\bar{q}_1, \bar{q}_2, \bar{q})\) where \(q\) is \(u\) or \(d\).

\[
M_{Y_{q_1,q_2,q_3,q_4}} \gtrsim M_{B_{(q_1,q_2,q)}} + M_{\bar{B}_{(\bar{q}_3,\bar{q}_4)}}
\]

In all the decays described in the table we have assumed that the pair created by the breaking of the string is a pair of light quarks. In general, if the mass of the tetraquark is high enough heavier pair can also be created. In particular a pair of \((s, \bar{s})\). In [14] the ratio of the widths of decays involving a creation of \((s, \bar{s})\) over that of \((u/d, \bar{u}/\bar{d})\) was found out to be \(\sim 0.3\) for example the excited state with \(n = 4\) in Table 1 can decay not only to \(\Lambda_c, \bar{\Lambda}_c\) but also to \(\Omega_c, \bar{\Omega}_c\).

The search for the V-baryonium states conjectured in this section should be based on identifying states that decay to a baryon and an anti-baryon. If fact we would
like to argue that this search may also lead to finding of baryons that have not been detected yet [49,50] like those of (bcs), (bcq), (bbs), (bbq). The fully heavy baryons as (ccc), (bcc), (bbb) are unlikely to be found from decays of V-baryonium, since those would require pair creation of heavy quarks.

7 Summary

In this note we studied the system of tetraquark candidates around X (6900) in analogy to the system that includes the Ψ(4360) and Y (4630)/Ψ(4660). The latter was conjectured in [9] to be a system of V-baryonium tetraquarks, which we argue is the case also for the new states.

The smoking gun for this conjecture would be to observe higher excited states predominantly decay into a baryon and anti-baryon. In this note, complementing the discussion of [9], we account also for a decay mechanism involving annihilation of the BV and anti-BV in the tetraquark, for the ground and other lower states that are too light to decay to the baryon–anti-baryon pair, or have limited phase space to do so.

Another signature of this conjecture is the HISH modified Regge trajectories associated with each V-baryonium state. Using the HMRTs we can predict the masses of excited states, both orbital and radial excitations. The excited V-baryonium tetraquarks would predominantly decay to a baryon–anti-baryon pair, and we would like to encourage experiments looking at these channels.

The proposed upgrade of BEPCII, which will allow the BESIII experiment to access energies up to 4.9 GeV is a perfect opportunity to revisit the Y (4630)/Ψ(4660) state in the Λc ¯Λc channel [51]. Initial measurements near the threshold reveal some discrepancies with Belle data [52]. Furthermore, we predict an excited J^P^C = 1^- state at around 4870 MeV, which should decay predominantly to Λc ¯Λc, which is still in that range. The threshold of Λc Σc at 4.74 GeV will also be accessible, so one could potentially discover also a tetraquark state that decays to those baryons.

The X (6900) opens a new range for future experiments [53,54]. The unconfirmed second resonance X (7200) is at the right mass to be a radial excitation of X (6900). The lower, wider resonance around 6490 MeV also fits the same HMRT. The X (7200) is interesting being very near the threshold for decay to Ξ_bc and Ξ_c. A confirmation and accurate measurement of its properties will be important in understanding the system. The next excitation, which would decay predominantly to the doubly charmed baryon pair, is predicted at around 7500 MeV. It should not be much wider than X (7200).

There are also many open questions regarding tetraquarks and the stringy model of the V-baryonium. Let us list some here.

- A natural question about the HISH construction of exotics, is what about exotic hadrons other than tetraquarks, such pentaquarks, hexaquarks, and so on. In [9] we schematically described other stringy constructions of exotic hadrons. The quest for more complicated exotics requires further investigation. For example one can construct an exotic hexaquark using three BV with three diquarks, all connected through an anti-BV such that in total we get an object of baryon number 2 and with six quark endpoints. This object may related to the exotic hadron discussed in [55,56].

- Whereas quarks and strings (flux tubes) are well understood in QCD the BV is much less familiar. In holography it is described as a D_0 brane or a fractional D_0 brane, namely a D_p brane wrapping a p-cycle. It carries the baryon number charge. Other properties like its mass, the structure of the diquark as a BV and two short strings, or the annihilation process of BV with anti-BV all deserve further study. In QCD it is also referred to as a string junction (see [57] for a recent review), and is an important ingredient in some phenomenological models, e.g. in [39].
• One of the major open questions regarding exotics regards the existence of tetraquarks made up of light quarks only. It is probable that exotic tetraquarks are simply more stable for hadrons that include heavy flavor quarks. In the string model, the decay mechanism of breaking up of the string is not very sensitive to whether the endpoints are light or heavy. However the other decay channel via annihilation of the BV and anti-BV may have higher probability when there are light diquarks attached to the annihilating pair. By this argument the V-baryonium made up solely of light quarks would be wide and hence difficult to detect. This explanation deserves further investigation.

• Very recently, an open flavor tetraquark candidate has been observed [15–17]. These are two states with spins 0 and 1, both with a mass of around 2.9 GeV, and with the quark content $c\bar{s}d$. Since the HISH model describes hadrons of both light and heavy quarks, this tetraquark could also be described using the same stringy model used in this note. For this system the relevant baryon–antibaryon threshold is of $\Xi^+_c\bar{p}$ or $\Xi^0_c\bar{n}$ at 3400 MeV.

Acknowledgements

We would like to thank Marek Karliner for informing us about the new discovery and to Avner Soffer for useful discussions. This work was supported in part by a center of excellence informing us about the new discovery and to Avner Soffer for useful discussions.
