Submission date

ABSTRACT

We estimate the mass loss rates of photoevaporative winds launched from the outer edge of protoplanetary discs impinged by an ambient radiation field. We focus on mild/moderate environments (the number of stars in the group/cluster is $N \gtrsim 50$), and explore disc sizes ranging between 20 and 250 AU. We evaluate the steady-state structures of the photoevaporative winds by coupling temperature estimates obtained with a PDR code with 1D radial hydrodynamical equations. We also consider the impact of dust dragging and grain growth on the final mass loss rates. We find that these winds are much more significant than have been appreciated hitherto when grain growth is included in the modelling: in particular, mass loss rates $\gtrsim 10^{-8} M_\odot$/yr are predicted even for modest background field strengths ($\gtrsim 30 G_0$) in the case of discs that extend to $R > 150$ AU. Grain growth significantly affects the final mass loss rates by reducing the average cross section at FUV wavelengths, and thus allowing a much more vigorous flow. The radial profiles of observable quantities (in particular surface density, temperature and velocity patterns) indicate that these winds have characteristic features that are now potentially observable with ALMA. In particular, such discs should have extended gaseous emission that is dust depleted in the outer regions, characterised by a non-Keplerian rotation curve, and with a radially increasing temperature gradient.

Key words: accretion, accretion discs — circumstellar matter — protoplanetary discs — hydrodynamics — planetary systems: formation

1 INTRODUCTION

There is observational evidence that the environment of star forming regions can significantly affect the evolution of protostellar and protoplanetary discs. Until recent years the only evidence of such interplay has come from single objects showing clear signatures of an on-going interaction between their disc and the ambient environment (e.g. O’Dell, Wen & Hu 1993, Bally, O’Dell & McCaughrean 2000, Vicente & Alves 2005). With the advent of sub-millimetre surveys, we can now start accessing statistical samples of relevant properties of protoplanetary discs (mostly their mass and outer radius) and infer whether they do show imprints of being affected by the environment. Such studies have shown that this is indeed the case in the most extreme star forming region within 500 pc from us, the Orion Nebula Cluster (ONC). In this cluster, de Juan Ovejar et al. (2012) have suggested that typical disc sizes decrease as a function of the stellar surface density of the environment in which they are embedded. Even more interestingly, Mann et al. (2014) (see also Mann & Williams 2010) have shown that the dust component of discs tends to be less massive in the immediate vicinity of the dominant O star in the ONC, $\theta^1$ C. Mann et al. (2015) have not observed such a trend in another O-stars bearing cluster, NGC 2024. For milder star forming regions, we still lack observational evidence of how important the environment can be in shaping the structure and the evolution of discs. Upcoming spatially resolved surveys of discs might be able to clarify this. Earlier studies have analysed whether disc frequency depends on distance from the most massive stars in OB stars-bearing clusters. Most of them agree that in the close proximity to the luminous O stars, disc fraction declines by a factor of $\sim 2$. This trend has been observed for example in NGC 2244 (Balog et al. 2007), in NGC 6611 (Guarcello et al. 2007, 2009), in NGC 6357 (Fang et al. 2012) and in Cyg OB2 (Guarcello et al. in prep.). However, these results are still controversial: for example, Richert et al. (2015) have recently argued that such decreasing trend in disc fraction could be enhanced by sample incompleteness in some of these studies. In less populous clusters,
in which the number of sources near O stars is smaller, a more robust result is that no evidence of spatial gradient is observed (e.g. Roccatagliata et al. 2011).

There are two main environmental mechanisms that can affect protoplanetary discs: star–disc interactions, and photoevaporation. In dense clusters, during the lifetime of a disc (∼3–10 Myr, e.g. Haisch, Lada & Lada 2001; Mamajek 2009; Fedele et al. 2010), gravitational encounters with other stars may perturb the disc, truncating it to a defined outer radius, and steepening the surface density profile (see Hall 1997; Breslau et al. 2014; Rosotti et al. 2014; Vincke, Breslau & Pfalzner 2015 and references therein). Very few objects that might be undergoing such encounters have been detected (Salyk et al. 2014; Cabrit et al. 2006; Dai et al. 2015), since the timescale of observability is very short.

An arguably more important mechanism is the photoevaporation caused by the energetic radiation permeating the young associations. When stars form in groups, EUV (Extreme Ultraviolet) and FUV (Far Ultraviolet) radiation of the most massive stars heats the outer regions of protoplanetary discs, and can drive a gaseous flow from the disc surface (Hollenbach et al. 1994; Adams et al. 2004, hereafter A04). Such a scenario has been very successful in explaining the so-called ‘proplyds’ (Johnstone, Hollenbach & Bally 1998; Störzer & Hollenbach 1999; Richling & York 2000), i.e. dark silhouette discs or cocoon-like structures observed in star forming regions. Such objects have been observed for example in the ONC (O’Dell, Wen & Hu 1993; Bally, O’Dell & McCaughrean 2000), in Cyg OB2 (Wright et al. 2012), in Carina (Smith, Bally & Morse 2003), and in other star forming regions showing massive OB associations (i.e. luminous sources of high energy radiation). When the UV flux impinging onto the discs is less severe than in these star forming regions, the effect of such mass loss on the evolution of protoplanetary discs, and the impact on their planet formation potential, is however rarely considered.

To be more quantitative, external photoevaporation can be summarised in three different regimes. When the EUV component is dominant, due to the proximity of a massive O star (e.g. θ1C in the ONC), the EUV flux reaches the surface of the disc, heating it up to ∼10^4 K. A completely ionised flow is formed, driving gas outwards and photoevaporating the disc (Hollenbach et al. 1994). When the EUV flux is less severe, the FUV field can generate a neutral wind that is optically thick to the EUV radiation, since the FUV component has a larger penetrating depth than the EUV one. When this is the case, two different regimes may occur, depending on the disc size R0. We define the gravitational radius R_g of the disc as the radius at which the thermal energy is equal to the gravitational binding energy (equivalently, as the radius at which the sound speed is equal to the escape velocity):

$$R_g = \frac{GM_s\mu m_H}{k_\text{B}T} \approx 140 \text{ AU} \left(\frac{T}{1000 \text{ K}}\right)^{-1} \left(\frac{M_s}{M_\odot}\right),$$

where T is the temperature, M_s is the mass of the central star, and μ the mean molecular weight (in this case we used atomic gas with μ = 1.3). When R0 > R_g, the wind is launched supersonically (e.g. Johnstone, Hollenbach & Bally 1998). Such discs are defined to be supercritical. However, moderate FUV fields are not able to heat up the outer regions of discs to high enough temperatures such that R_g < R0. A04 have shown that when this is the case, the flow structure can be described by a non isothermal Parker wind, with the addition of a centrifugal term. This model uses the reasonable assumption that the mass loss rate from the outer rim of the disc dominates the mass loss rate from the surface of the disc (see the Appendix in A04), where the gas is more embedded in the gravitational potential well of the central star. Since the outer regions of discs contain the bulk of the mass and since the rate of disc evolution is determined by the outer disc radius, such external winds have important implications for disc lifetimes and surface density profiles. Indeed, as noted by Clarke (2007) and confirmed by Anderson, Adams & Calvet (2013), such winds accelerate disc clearing not on account of the mass lost in the wind (which is a fraction of that accreted onto the star over the disc lifetime) but instead because they modify the disc’s outer boundary, preventing disc spreading and keeping the viscous timescale relatively short.

Lada & Lada (2003), Porras et al. (2003) and others have shown that the probability density function for cluster membership number N for clusters in the Solar Neighbourhood scales with 1/N^2. Therefore the cumulative probability for a star to be born in a cluster of size ≤ N is inversely proportional to N (e.g. Adams 2010). Within 2 kpc of the Sun, the median value of this distribution (also taking into account isolated stars) is ∼300 (Adams et al. 2006; Allen et al. 2007). The majority of protoplanetary discs are then very likely to evolve embedded in relatively ‘mild’ (low N) environments. Clusters and groups with N ≤ 500 have typical FUV fields G_{FUV} < 3000 G (e.g. Fatuzzo & Adams 2008), where G0 is the local FUV interstellar field (1.6 × 10^{-2} erg s^{-1} cm^{-2}, Habing 1968). Fatuzzo & Adams (2008) have also shown that the FUV flux depends strongly on the most massive star in the cluster, and on the intra-cluster column density of absorbing material. Stars in small groups (∼50 – 100) are likely to be impinged by an environmental FUV field of ∼30 – 300 G0, i.e. slightly larger than the local field. The majority of protoplanetary discs are then very likely to lie in the subcritical regime of external photoevaporation, at least in the Solar Neighbourhood.

Note that at such low values the external radiation becomes comparable to the radiation from the central star even at large radii (e.g. Bergin et al. 2003). In particular, France et al. (2014) looked at a sample of CTTSs and estimated the FUV field close to the central object by deriving the FUV continuum and hot gas lines profiles from high spectral resolution HST observations at FUV wavelengths. They obtained FUV fields of ∼10^2 G0 at ∼1 AU, which are due to both stellar and accretion contributions. By considering geometrical dilution only, FUV fields of 300 and 30 G0 are thus expected at 180 and 580 AU, respectively. However, the bulk of the disc is shielded by its inner regions, especially for low flaring angles, and most of the radiation is absorbed ∼2 scale-heights above the midplane, as shown in thermo-chemical models (for example, Bruderer et al. 2012) that compute an FUV intensity of ∼100 G0 at ∼100 AU and z/R ∼ 0.2 for HD 100546). Besides, the midplane of the outer disc can be directly impinged by the ambient radiation, and gas can be removed more easily. Thus in the outer regions of discs external photoevaporation could play a dominant (or at least comparable) role with respect to the photoevaporation driven by the FUV radiation of the central star (Gorti & Hollenbach 2009; Gorti, Hollenbach & Dullemond 2015). Evidently this is an issue that will only be finally settled using 2D radiation hydrodynamical simulations including both internal and external FUV sources.

The subcritical regime of external photoevaporation is the most difficult to probe observationally. However, there are some observed signatures that might be indicating that such a mechanism is occurring even in quite isolated systems (i.e. very low external UV fluxes). A potential example of this is the disc around IM Lup. Pančić et al. (2009) have shown that outside the mm-bright disc (R_{out,dust} = 400 AU; Pinte et al. 2008), the gas structure as probed by CO emission lines indicates a steep decrease in the surface density profile, which resembles the profiles obtained by A04 in their...
reaches the critical radius $R_c$, where the flow velocity is close to the sound speed. From this point onwards the velocity of the wind is approximately uniform. In this subcritical regime, the mass loss from the disc’s outer rim is more significant than the mass loss from the disc surface.

flow models. Oberg et al. [2015] have also detected a DCO$^+$ double ringed structure, which could be tracing a radially increasing temperature gradient in the outer regions of the disc in agreement with the predictions from external photoevaporative models (though the authors interpret the data in terms of non-thermal desorption of CO ices). Note that similar features are also predicted by photoevaporation models where the winds are driven by the FUV field emitted by the central star and by the accreting material (Gorti & Hollenbach 2009; Gorti, Hollenbach & Dullemond 2015). From simple calculations of external photoevaporation models the gas flow in the outer regions of this disc would be highly dust depleted, since the drag force is very weak for the large grains probed by submm observations, and such an effect is compatible with the dust depleted outer regions of the disc. There are other systems where this second effect (a radially decreasing dust-to-gas ratio, as probed by line/continuum size discrepancies) is observed (e.g. Pétrus, Dutrey & Guilloteau 2007; Andrews et al. 2012; Rosenfeld et al. 2013; de Gregorio-Monsalvo et al. 2013). Note however that Birnstiel & Andrews (2014) have shown that such discrepancies can also be explained by the size-dependent radial drift of dust particles, without appealing to an outer disc wind. We will suggest alternative observational diagnostics that can discriminate between the two scenarios.

In this paper, we firstly aim to compute the mass loss rates of discs affected by external photoevaporation in the subcritical regime, by extending the parameter space investigated by A04 to larger (but still subcritical) discs, and milder ambient fields. Our method of solution broadly follows that of A04 but with some important differences relating to the effect of non-isotropy in correctly locating the critical point of the flow. We also iterate towards a self-consistent solution which takes into account the fact that only small grains are entrained in the flow. Note that the effect of partial entrainment of dust grains upon the thermal structure of the flow has been recently applied to the internal photoevaporation scenario by Gorti, Hollenbach & Dullemond (2015). We finally present typical radial profiles of the main hydrodynamical quantities, and propose potential observational signatures of ongoing photoevaporation in this subcritical regime.

The paper is structured as follows. In Section 2 we briefly summarise the photoevaporative model by A04 and explain how our description differs from theirs. In Sections 3-5 we detail the main ingredients of our model; respectively the thermal properties, gas hydrodynamics, dust hydrodynamics, and the iteration procedure to obtain the final solutions. In Section 6 we present our results, which are then discussed in Section 7. In Section 8 we summarise our conclusions.

### 2 COMPARISON WITH PREVIOUS WORK

We consider the subcritical regime ($R_d < R_k$) previously investigated by A04 and assume that the disc is irradiated by an isotropic FUV ambient radiation. A04 have shown that the ratio between the mass loss rate from the disc surface $M_{\text{surf}}$ and the mass loss from the disc edge $M$ scales as $M_{\text{surf}}/M \sim (R_d/R_k)^{1/2}$. Since they focus on the subcritical regime, where $R_d < R_k$, the mass loss rate is dominated by the radial flow emerging from the outer rim of the disc, and not by the material flowing from its surface. Thus the subsonic wind can be described with a 1D radial model (see Fig. 1 for a schematic of the model). A04 computed the temperature as a function of local gas density $n$ and FUV (from the ambient radiation) optical depth $\tau$ by using the photo-dissociation region (PDR) code by Kaufman et al. [1999]. They then coupled this temperature dependence with the steady state momentum/continuity equations in order to iteratively find a self-consistent steady state solution of the gaseous flow. The model we present in this paper is very similar to the one proposed by A04 but contains some key differences, that will be described in more detail between Sections 3-5.

(i) We take deviations from isothermality into account in locating the critical point of the flow, in contrast to A04 who impose the condition that the flow is transonic at the location corresponding to the sonic point for isothermal gas. This self-consistent location of the critical point results in a different location and local flow velocity at this point compared with the isothermal solution. Our results demonstrate that this difference is the most important one, since it modifies mass loss rates significantly. Having located the critical point of the flow we are able to integrate inwards to the disc edge (in contrast to A04 who adopt an iterative scheme in integrating outwards from the disc edge).

(ii) The self-consistent location of the critical point allows us to obtain solutions over a larger range of parameter space than A04. Specifically we are able to find solutions for lower values of the interstellar field $G_{\text{FUV}}$ (i.e. down to $30G_0$) and for a wider range of outer disc radii (out to $R_d = 250$ AU).

(iii) Having determined a flow solution at fixed dust to gas ratio we then take account of the fact that only the small grains are entrained in the flow and re-compute the flow solution implementing the reduced dust to gas ratio in the flow.

(iv) Our code computing the temperature structure is different from A04. (see Section 3 below).

### 3 TEMPERATURE ESTIMATES - PDR

FUV radiation ($6 \leq \lambda \nu \leq 13.6$ eV) plays a crucial role in determining the thermal structure and corresponding chemistry in so-called photodissociation regions (PDRs) where gas undergoes a transition between ionised and molecular state. If a disc is interacting with an ionising radiation field impinging externally, then
between the ionisation front (if present) and its dense gas, the region is optically thin to FUV radiation but optically thick to EUV radiation ($h\nu > 13.6\text{ eV}$). This causes the gas to be in a state of partial dissociation where the temperature is set by the FUV radiation field. Under these conditions, determination of the gas temperature requires modelling of various heating and cooling processes in terms of a complex and non-linear set of differential equations describing a network of chemical reactions. In the last two decades, many groups have managed to develop numerical codes that are able to solve such problems (see Rollig et al. 2007, for a paper detailing inter-comparison between such codes). Below we describe the 3D-PDR code (Bisbas et al. 2012) that we use to obtain the gas temperature as a function of column density, grain opacity, local gas density and FUV field.

### 3.1 3D-PDR

The 3D-PDR code (Bisbas et al. 2012) is a three-dimensional time-dependent code treating photodissociation regions of arbitrary density distribution. Using an iteration scheme it solves the chemistry at every cell consisting of the gaseous structure until thermal and chemical equilibrium has been reached. 3D-PDR uses a set of various heating and cooling functions fully described in Bisbas et al. (2012), and shown in Fig. 2 for a specific case. The code has been used in various one-dimensional (Bisbas et al. 2014), Bisbas, Papadopoulos & Viti (2015) and three-dimensional (Offner et al. 2013, 2014; Gaches et al. 2015) applications. The 1D version of the code UCL-PDR has been benchmarked with many other PDR codes (Rollig et al. 2007).

In this paper, we have adopted the code modifications described in Bisbas et al. (2014). We use a reduced version of the UMIST 2012 network (McElroy et al. 2013) which contains 33 species (including $e^-)$ and 330 reactions. Table 1 shows the initial abundances used by the 3D-PDR code at the beginning of the calculations (taken from Asplund et al. 2009). Using the full chemical network of 215 species causes difference in the temperature by up to $\sim 10$–15%. Since other unknown parameters (such as polycyclic aromatic hydrocarbon abundances, see below) lead to even larger uncertainties, we opted for the reduced network to save computational time. We consider one-dimensional uniform density profiles with $10^2 < n < 10^5\text{ cm}^{-3}$ interacting with radiation fields of 30, 300 and $3000 G_0$. The spatial extent of each density profile is chosen so that the visual extinction, $A_V$, is in the range $10^{-7} \lesssim A_V \lesssim 10$. Density is sampled every 0.1 dex, and $A_V$ every 0.05 dex. The results are then interpolated with cubic-spline functions to a much finer grid. The cosmic ray ionisation rate, $\zeta_{\text{CR}}$, is taken to be $\zeta_{\text{CR}} = 5 \times 10^{-17}\text{ s}^{-1}$. The treatment of PAHs is discussed in the next Section. We evolve the chemistry in each simulation for 10 Myr. We have checked that the temperature balance is reached on shorter timescales, $\sim 10$ ky. A posteriori, we have verified that the flow timescale is always longer than 10 ky, thus temperature balance within the flow is a reasonable assumption.

### 3.2 Dust and PAHs

Dust plays a key role in the determination of the gas temperature. For example, for the density range addressed here, the main heating mechanism of the gas is usually photoelectric heating from the atomic layers of PAHs (e.g. Weingartner & Draine 2001, Croxall et al. 2012), but it can also affect the temperature through other mechanisms such as H$_2$ formation and gas-grain collisions. Secondly, dust can have a significant impact on the chemistry, which eventually sets the abundances of the main coolants, e.g. by controlling the amount of ices. Note that all these mechanisms depend on the total surface area of dust grains. Finally, dust sets the attenuation of the FUV radiation via the penetrating depth $\tau$, where we set $\tau = 1.8A_V = N_H/\sigma_{\text{FUV}}$ and $N_H$ is the hydrogen column density. A detailed description of this effect will be described in Section 5.

Typical interstellar dust can be modelled with a simple distribution $d\phi/ds \propto s^{-q}$, where $\phi$ is the number density of dust particles, and $s$ is the grain size. It is well known that in the interstellar medium $q$ assumes a typical value $q \sim 3.5$ (historically labelled as MRN distribution, from Mathis, Rumpl & Nordsieck 1977).
Figure 3. Gas temperature as a function of visual extinction $A_V$ for three different values of the ambient FUV field: 30, 300 and 3000 $G_0$, from top to bottom. The left panels are associated to a grain size distribution with maximum grain size $s_{\text{max}} = 3.5 \mu m$, the right panels to a distribution with $s_{\text{max}} = 1 \text{ mm}$. Line colours indicate different gas numerical densities $n$, ranging between $10^2 - 10^6$ cm$^{-3}$ (the legend is reported in the right top panel).

recently, interferometric observations have suggested a shallower distribution in the optically thin regions of protoplanetary discs at submm - mm wavelengths, where $q \sim 2.5 - 3$ (e.g. Ricci et al. 2010a,b, 2012, and references therein), to sizes $\gtrsim 1 \text{ mm}$. Grain growth can alter the heating and cooling processes mentioned above.

The only observation indirectly constraining the grain size distribution within the photoevaporative winds is by Störzer & Holtenbach (1999), who estimated the cross section in supercritical winds at FUV wavelengths from the location of the ionisation front around proplyds in Orion. Their best estimate is $\sigma_{\text{FUV}} =$...
We compute the cross section at FUV wavelengths ($\lambda = 0.1\,\mu m$) for an ISM-like dust distribution ($q = 3.5$ and $s_{\text{max}} = 0.25\,\mu m$), see e.g. [Draine 2011] using the code described in [Wyatt & Dent 2002] (see their section 4.1). We use the optical constants from [Li & Greenberg 1997], for iceless silicate grains with a porosity of 0.3. The absorption coefficients of the grains $Q_{\text{abs}}(\lambda, s)$ are computed using Mie theory [Bohren & Huffman 1983, Rayleigh-Gans theory or geometric optics in the appropriate limits [Laor & Draine 1993]. Assuming a dust-to-gas ratio to $10^{-2}$ we obtain a cross section $\sigma_{\text{FUV}} \approx 2.6 \times 10^{-21}\,\text{cm}^2$, as expected. We then determine the maximum grain size of a distribution with $q = 3.5$ that has an associated cross section 0.3 times smaller than the ISM-like one. The best fit gives $s_{\text{max}} = 3.5\,\mu m$. This result confirms that the estimates by [Störzer & Hollenbach 1999] are probing moderate grain growth.

In the PDR code (and throughout the whole paper), we consider two MRN distributions ($q = 3.5$) with maximum grain sizes $s_{\text{max}} = 3.5\,\mu m$ and $s_{\text{max}} = 1\,\text{mm}$. We fix the dust-to-gas ratio to $10^{-2}$. The first distribution is chosen as to give the same cross section used by [A04] in their models, in order to have a direct comparison with their results. The second distribution represents a disc where substantial grain growth has occurred, and the population of small grains, which contribute the most to the dust surface area when $q > 3$, is reduced by a factor $\sim 10^2$.

Polycyclic Aromatic Hydrocarbons (PAHs) are the dominant heating source, since photons are very efficient in removing electrons from such mono-layered molecules. However, the amount of PAHs in protoplanetary discs is not well constrained by observations. Infra-Red observations from Spitzer and from the ground have revealed strong PAH emission features in some Herbig Ae/Be stars, whereas very few T Tauri stars have shown them at a detectable level [Geers et al. 2006 and references therein]. This difference is probably due to the more intense UV field emitted by the Ae/Be stars (e.g. Visser et al. 2007) exciting the PAHs. For the same reason, PAH emission is spatially concentrated in the inner region of the discs, where the UV flux from the central star is higher [Geers et al. 2007, Maaskant et al. 2014]. PAH abundance in discs is still being debated. Observations (e.g. Geers et al. 2006, Oliveira et al. 2010) tend to indicate that PAH-to-dust mass ratio in discs is $\sim 10\%$ of the PAH-to-dust mass ratio in the galactic ISM, which is $\approx 4 \times 10^{-2}$ [Draine & Li 2007, Tielens 2008], but the estimate is poorly constrained. In thermo-chemical disc models, different values of PAH-to-dust mass ratio have been used in the literature, e.g. $0.5 \times 10^{-2}$ [Bruderer et al. 2012], or $1.3 \times 10^{-2}$ [Woitke et al. 2015]. Because of the level of the uncertainties in this value, we simply fix the PAH-to-gas mass ratio to $2.6 \times 10^{-4}$, as in [Wolfire et al. 2003], since we use their prescription to compute the photoelectric heating. For the dust-to-gas ratio of $10^{-2}$ used in this paper, this value yields a PAH-to-dust mass ratio of $2.6 \times 10^{-2}$.

Another debated topic is whether grain growth affects the amount of PAHs, i.e. whether they should scale according to the amount of small grains. This is still largely unconstrained. As an example, one of the strongest PAH emission features is observed in Oph IRS 48 [Geers et al. 2007], where grain growth has certainly occurred (e.g. van der Marel et al. 2013). Even though some recent models (e.g. Gorti, Hollenbach & Dullemond 2015) assume a reduced PAH abundance when small grains are depleted by effective grain growth, in this paper we prefer to keep the PAH abundance fixed, since there is no clear observational indication that PAHs would follow the small grains.

In order to compute the photoelectric heating due to PAHs, we adopt the treatment by [Bakes & Tielens 1994], with the additional modifications suggested by [Wolfire et al. 2003] (with the $\phi_{\text{PAH}}$ factor defined in their equation 21 equal to 0.4).

### 3.3 Results

Fig. 3 shows the results of the 3D-PDR code for FUV fields of 30, 300 and 3000 $G_0$, for the two grain size distributions. We present the gas temperature as a function of visual extinction $A_V$, for logarithmically sampled values of gas density $n$. As expected, the gas temperature increases with intensity of the external radiation. At a given $G_{\text{FUV}}$, for the parameters we have chosen, temperature is usually a decreasing function of visual extinction $A_V$. For $s_{\text{max}} = 3.5\,\mu m$ temperature does also increase with $A_V$ in the marginally optically thick regime, when $n \sim 10^9 - 10^4\,\text{cm}^{-3}$. Similarly, temperature is not a monotonically decreasing function of density $n$. This non-monotonic behaviour is a well known result in PDR codes [Kaufman et al. 1999].

These results depend on the metallicity and on the dust-to-gas ratio, since they both regulate the heating and cooling functions. In particular, reducing the amount of small grains has the net effect of slightly decreasing the temperatures, as we can see comparing the temperatures obtained with the two different dust distributions. The smaller dust total surface area reduces some heating mechanisms, such as photoelectric heating, $H_2$ formation rate and $H_2$ photodissociation. However, the total heating is still dominated by the photoelectric effect on PAHs. Cooling is not affected significantly, since the main coolants are $\text{C}_1$ and $\text{O}_1$ in the optically thin regime (see Fig. 2). The net effect is that temperature is not affected significantly by the total amount of small grains, provided that the PAH abundance is kept fixed. The only exception is apparent in the high density and high FUV flux case ($n = 10^6$ and $G_{\text{FUV}} = 3000\,G_0$). In this regime, heating from FUV pumping of $H_2$ molecules becomes comparable to the photoelectric heating [Hollenbach & Tielens 1999, A04]. The abundance of $H_2$ molecules depends on the $H_2$ formation rate, which depends on the total dust surface area. By reducing the amount of small grains, $H_2$ formation rate drops, and so does the FUV pumping, resulting in a lower temperature.

For the cases considered here and displayed in Fig. 3 at fixed density the temperature always shows a plateau at low optical depths, and then decreases steeply with visual extinction, until it approaches unity and the gas becomes optically thick to the external radiation. These two characteristics will shape the final profiles of the subsolar winds. Finally, the temperatures are lower than the ones computed by [A04] (e.g. by a factor $\sim 2$ when $G_{\text{FUV}} = 300\,G_0$, in the regions of parameter space that overlap, even in the hottest case when $s_{\text{max}} = 3.5\,\mu m$). For the same dust distribution, we obtain temperatures similar to the ones by [Kaufman et al. 1999] (and therefore by A04, who use the same PDR code) by using the prescription by [Bakes & Tielens 1994] (without the correction by Wolfire et al. 2003) for the PAH photoelectric heating. In particular, we reproduce the same trend observed by Kaufman et al. 1999 in their fig. 1.
4 HYDRODYNAMICS

In the last section we have shown how to derive the temperature of the gas in the PDR region as a function of local density \( n \) and visual extinction \( A_V \). We now want to couple these results to the hydrodynamical equations describing the flow departing from the edge of a protoplanetary disc.

4.1 Equations for the wind structure

We develop a 1D description of the problem in a quasi spherical geometry, where we self-consistently solve for the radial steady-state structure of the wind launched from the disc outer edge. The equations shown in this section are based on the similar model by A04.

The time independent version of the continuity equation is:

\[
\dot{M} = 4\pi R^2 F \mu m_H n v,
\]

where \( m_H \) is the hydrogen atom mass and \( v \) is the velocity of the gas. \( F \) is the fraction of the solid angle subtended by the disc outer edge (see equation 14 by A04). The flow might be not perfectly spherical, since the wind might not be pressure confined at the boundaries of the wedge defined by the solid angle \( 4\pi F \). We could model the flow with a hyper-spherical continuity equation, where \( M \propto R^n \) and \( n > 2 \) (\( \alpha = 2 \) defines the spherical case, see equation 3). For simplicity, we consider the spherical case only in this paper.

Similarly, the time independent momentum equation is:

\[
\frac{dv}{dR} + \frac{1}{\rho} \frac{dP}{dR} + \frac{GM_R}{R^2} - \frac{\beta^2}{R^3} = 0,
\]

where \( \beta^2 = GM_R \rho_0 \). We are considering a flow with uniform specific angular momentum, given by the Keplerian angular momentum at the outer radius of the disc. We assume an ideal gas law for the pressure \( P = n_k T \), where \( T \) is a function of density and optical depth (as shown in Section 4.2).

Following A04, we can express the above equations in a dimensionless form, where our parameterisation choice is slightly different. We define \( \xi \equiv R/R_a \), \( f \equiv T/T_c \), \( g \equiv n/n_c \) and \( u \equiv v/e_{\infty,c} \), where \( e_\infty \) is the sound speed of the gas. With the subscript \( c \) we indicate quantities evaluated at a critical radius, where \( f \) is coincident with the temperature \( T_c \) and \( g \) with the number density \( n_c \) at this point for which the mass loss rate and flow structure for a given disc in a given environment (cf. A04). This however requires iterative solutions for various guessed flow velocities at \( R_a \) and is not a preferred method in the case where the critical point conditions are themselves a function of the flow solution. Since we start each flow solution from the self-consistently determined critical point of the flow, it is operationally convenient to use \( T_a \) as the independent variable. Each solution can then be mapped onto the corresponding value of the pressure at the disc outer edge.

In order to evaluate the critical radius for a given value of \( T_a \), we proceed as follows. We first guess the value of the critical radius (i.e., as parametrised by \( \xi_c \)); for an initial guess we take the re-scaled sonic radius \( \xi_s \). Using the isothermal limit of equation

\[
\xi_s = \frac{\beta}{4} \left[ 1 + \left( \frac{1 - 8}{\beta} \right)^{1/2} \right],
\]

and noting that \( \beta \) is fixed for given \( T_a \) by equation 8.

Once we have an initial guess for the critical radius, for every iteration on the value of \( \xi_c \) we calculate the pair of values for the number density and optical depth at this point for which the PDR models predict that \( T = T_c \) locally. This step requires an assumption about the density structure of the flow outside the critical
radius. Here we follow Johnstone, Hollenbach & Bally (1998) and A04 in assuming that the velocity is approximately constant in this region so that from the continuity equation we then obtain:

$$n(R) = n_c \left(\frac{R_c}{R}\right)^2, \quad \text{for } R > R_c,$$

and consequently

$$\tau_c = \sigma_{FUV} \int_{R_c}^{\infty} n_c \left(\frac{R_c}{R}\right)^2 dR' = \sigma_{FUV} R_c n_c.$$  

(12)

Figure 4 gives an example of $T_c$ as a function of $\tau_c$ for an initial guess $R_c \sim 500$ AU and for a range of FUV fluxes. For low FUV fluxes, there are no solutions in the low optical depth range ($\tau < 10^{-3}$). This constraint is set by the lower limit we have implicitly imposed on the density, when we have not dealt with anything less dense than $10^2$ cm$^{-3}$ in Section 3.

We are now able to determine $\tau_c$ and $n_c$ by solving the equation:

$$T_c - T(\tau_c) = 0.$$  

(13)

We can evaluate the partial derivatives of $T$ with respect to density and optical depth (at fixed $R_c$) and use these in equations 8 and 9. We then solve for the next value of $R_c$ by solving equation 9 using a bisector method. We then iterate the whole process, until we reach convergence on the value of $\xi_c$. By doing so, we have obtained the critical radius, and we have the initial conditions for $T$ (given by the input parameter $T_c$), $v$, $n$ and $\tau$. The critical radius is always larger than the sonic radius (as defined by equation 10), but at the most by a factor of a few tenths of a dex (see an example in Fig 5). On the other hand, the critical velocity is usually smaller than the sound speed at the critical radius, by $\sim 20\%$ at the most (see an example in Fig 6). Finally, we can estimate the mass-loss rate $\dot{M}$ from equation 7. We are ready to start integrating equation 4 inwards, from the critical radius to the disc outer edge, in order to deduce the velocity profile of the subsonic flow between $R_d$ and $R_c$.

4.2.1 Extending the solutions

In the definition of the sonic radius (see equation 10), by construction we are requiring that $\beta > 8$. Thus we are implicitly setting an upper limit to the $T_c$ we can set at a given $R_d$:

$$T_c \leq \frac{GM_\odot \mu m_H}{8 k_B R_d} \simeq 873 \left(\frac{M_c}{M_\odot}\right) \left(\frac{20 \text{ AU}}{R_d}\right)^2 \text{K.}$$  

(14)

This strongly limits the explorable region of parameter space, when $R_d$ is large and the FUV flux (and therefore temperature) is high. In order to enlarge the parameter space, when $\beta < 8$, as a first guess for $R_c$ we choose the critical radius of the solution with the same $T_c$ and the closest value of $R_d$, showing a iteratively converged solution for the critical radius. In Fig 5 we show $R_c$ versus $T_c$ when $G_{FUV} = 30 G_0$, for a range of disc radii $R_d$ between 20 and 250 AU, sampled every 10 AU. The critical radius does not show a strong dependence on $R_d$, at fixed $T_c$. In this way we are able to obtain more solutions, even though in some regions of parameter space we do not manage to obtain one.
Figure 6. Ratio of critical velocity to the sound speed at $R_\text{c}$ for solutions with $G_{\text{FUV}} = 30 \, G_0$ and $s_{\text{max}} = 1 \, \text{mm}$, and $R_d = 20, 100$ and $180 \, \text{AU}$ (blue, black and green lines, respectively).

4.3 Method of solution

Once we have located the critical radius and determined the boundary condition for flow density, optical depth and velocity for a given $T_\text{c}$, a disc radius and a FUV flux $G_{\text{FUV}}$, we can integrate equation\(^7\) from $R_c$ to $R_d$ (in rescaled units, from $\xi_c$ to 1). We use a simple Euler code. At every step we compute $u_{i+1}$ from equation\(^7\) Then, we calculate dimensionless density $g_{i+1}$ from the dimensionless form of equation\(^8\) and $\tau_{i+1}$ from equation\(^5\). At given $g_{i+1}$ and $\tau_{i+1}$ we can compute the new temperature partial derivatives $\partial f/\partial g_{i+1}$ and $\partial f/\partial \tau_{i+1}$ from the PDR output, and therefore obtain the next value of the temperature $f_{i+1}$. With this set of equations we can self-consistently solve for the flow steady-state. We use an initially logarithmically spaced grid, since the absolute value of the gradient of most of the quantities increases as the solution approaches $R_d$. This happens mostly in the transition between the optically thin and the optically thick regime, when the temperature drops steeply (as shown in Fig 3). In order to better resolve this region we also apply an adaptive mesh algorithm, i.e. we require that $\Delta \xi$ is small enough to ensure that the relative change in velocity between two steps is less than $1\%$ ($|u_{i+1} - u_i|/u_i < 0.01$).

However, we need to apply slight modifications to the algorithm at the two boundaries of the integration, in the proximity of both the critical radius $R_c$ and the disc outer radius $R_d$.

4.3.1 The critical point

In Section\(^2\) we have defined the critical radius as the radius at which the r.h.s. of equation\(^7\) vanishes. Moreover, at this same radius the second multiplicant of the l.h.s. of the same equation is 0. Since we are starting integrating the same equation from $R_c$, we have a null value both at the numerator and at the denominator. This leads to the possibility of having multiple transcritical solutions (the analogue version of the transonic solutions in the standard isothermal case). More specifically, we will have a solution that will be supersonic between $R_d$ and $R_c$, and one solution that will be subsonic. We are looking for the second one. Therefore we need to enforce the solution to relax onto the subsonic branch. We do so by following a procedure that is similar to the one used by Murray-Clay, Chiang & Murray\,(2009) for an analogous problem.

We expand equation\(^7\) around the critical point to first order in both radius and velocity: $\xi = \xi_c + \delta \xi$, and $u = u_c + \delta u$. We obtain the following relation:

$$\frac{\delta u}{\delta \xi} \bigg|_{\xi_c} = -\frac{B + \sqrt{B^2 - 4AD}}{2A},$$

where:

$$A = 2u_c + \frac{2g}{u_c} \frac{\partial f}{\partial g} + \frac{9}{4} \frac{\partial^2 f}{\partial g^2};$$

$$B = 2\tau_0 \frac{\partial f}{\partial \tau} + \frac{8g}{\xi} \frac{\partial f}{\partial g} + \frac{4g^2}{\xi} \frac{\partial^2 f}{\partial g^2} + 2\tau_0 g^2 \frac{\partial^2 f}{\partial \tau^2};$$

$$D = u_c \left( \frac{2u_c^2}{\xi^2} - 2\frac{\partial f}{\partial g} + \frac{8g}{\xi} \frac{\partial f}{\partial g} + 4\tau_0 g \frac{\partial f}{\partial \tau} + 4g^2 \frac{\partial^2 f}{\partial g^2} + 2\tau_0 g^2 \frac{\partial^2 f}{\partial \tau^2} \right),$$

where all the quantities are evaluated at $\xi = \xi_c$. In equation\(^15\) we chose the positive root, in order to pick the subsonic solution at $\xi < \xi_c$.

Similarly to Murray-Clay, Chiang & Murray\,(2009), we calculate the velocity by using:

$$\frac{du}{d\xi} = F_{\text{exact}} \frac{du}{d\xi} \bigg|_{\xi = \xi_c} + (1 - F_{\text{exact}}) \frac{\delta u}{\delta \xi} \bigg|_{\xi_c},$$

where $du/d\xi|_{\text{exact}}$ is evaluated from equation\(^7\) and

$$F_{\text{exact}} = -\text{erf} \left[ h \left( 1 - \frac{f}{u^2} - \frac{g}{u^2} \frac{\partial f}{\partial g} \right) \right],$$

where erf is the error function. The parameter $h = 20$ gives the smoothing length of the transition between $du/d\xi|_{\text{exact}}$ and $\delta u/\delta \xi|_{\xi_c}$ when computing $u(\xi)$. We use this modified version of equation\(^7\) until $F_{\text{exact}} = 1$ to the level of machine precision.

4.3.2 Temperature corrections near $R_d$

Some solutions become completely optically thick before reaching the disc outer radius (i.e. $R > R_d$). In the PDR calculations, we have set a minimum temperature equal to 10 K. However, the temperature of the flow could be higher than that, due to the impinging radiation from the central star. When we compute the temperature of the flow, we therefore include heating from the central star, by using the following simple prescription:

$$T = \text{max} \left( T_{\text{PDR}}, T_{\text{rad}} \right),$$

where $T_{\text{PDR}}$ is the temperature evaluated via the PDR code (i.e. the one used so far in the paper), and $T_{\text{rad}}$ is given by:

$$T_{\text{rad}} = 100 \, \text{K} \left( \frac{R}{1 \, \text{AU}} \right)^{-1/2},$$

i.e. a temperature profile found to fit the spectral energy distributions of passive discs (e.g. Andrews & Williams\,(2005, 2007)).

5 DUST COMPONENT

In Section\(^3\) we have reported the equations and the procedure to obtain a solution for the gas quantities between the critical radius and the disc’s outer edge. However, this solution depends on the dust properties within the flow. In particular, as mentioned in Section\(^3\), the attenuation factor strongly depends on the grain size...
distribution and on the maximum grain size \( s_{\text{entr}} \) entrained in the wind. Such dependence can be summarised in how \( \sigma_{\text{FUV}} \) is related to these two properties of the dust material. In this section, we also describe the hydrodynamical equations for the dust particles, which will be used to determine the maximum grain size entrained in the flow, and thus the cross section.

5.1 Cross section

It is well known that protoplanetary discs witness substantial grain growth in the discs’ midplane (see Section 3.2). Such grain growth can be schematised in two effects: producing a shallower distribution, i.e. a lower \( q \), and leading to a larger maximum grain size \( s_{\text{max}} \). As introduced in Section 3.2, in this paper we focus on two distributions with the same power law index \( q = 3.5 \) but different maximum grain sizes \( (s_{\text{max}} = 3.5 \mu m \) and \( 1 \) mm). The same distributions have been used to compute the dependence of the temperature on \( n \) and \( A_V \). As mentioned above, we consider a dust-to-gas ratio of 0.01 for both the distributions.

We compute the cross section at FUV wavelengths (\( \lambda = 0.1 \mu m \)) using the code of [Wyatt & Dent (2002)] as briefly described in Section 3.2. In the equations reported below, we describe a general treatment where \( q \) can assume different values. We take into account that there is a maximum grain size entrained in the photo-evaporative wind, and we compute the cross sections for the truncated distribution:

\[
\sigma_{\text{FUV}} = \frac{\mu_{\text{HH}}}{m_{\text{entr}} \delta_{\text{gd}}},
\]

where

\[
q_s = \int_{s_{\text{min}}}^{s_{\text{entr}}} \pi s^2 Q_{\lambda, s} \rho d\lambda ds,
\]

\[
m_{\text{entr}} = \frac{4}{3} \frac{\pi}{4 - q} s_{\text{entr}}^{(4 - q)} - s_{\text{min}}^{(4 - q)},
\]

and

\[
\delta_{\text{gd}} = 100 \left( \frac{s_{\text{entr}}^{(4 - q)} - s_{\text{min}}^{(4 - q)}}{s_{\text{entr}}^{(4 - q)} - s_{\text{min}}^{(4 - q)}} \right).
\]

In these equations, \( \delta_{\text{gd}} \) is the effective gas-to-dust ratio within the flow, and \( \rho \) is the mean mass density of a dust grain (in this paper 1 g/cm\(^3\)). The minimum grain size of the distribution has been set to \( s_{\text{min}} = 5 \times 10^{-7} \) cm in the whole paper.

The cross sections are reported in Fig. 7 as a function of the maximum grain size entrained in the flow, for \( s_{\text{max}} = 3.5 \mu m \) (red line) and \( s_{\text{max}} = 1 \) mm (black line). The cross section does not vary by much when the distribution is truncated to \( s_{\text{entr}} \gtrsim \lambda \), because the largest contribution to the cross section in the geometric limit comes from the smallest grains when \( q > 3 \). We do not re-compute the temperature \( T(n) \) with the PDR code for the new truncated distributions, since it depends weakly on the maximum grain size. As discussed in Section 3.2 this is due to the fact that heating is mostly generated by the photoelectric effect on PAHs and on small grains, since the total surface area per unit mass is dominated by the small grains of the distribution when \( q > 3 \). Cooling is not significantly affected by the absence of the largest grains, since O I and C II emission lines dominate the radiative cooling.

5.2 Fluid equations for dust particles

In order to obtain the maximum grain size entrained in a gaseous solution, we need to solve the hydrodynamical equations of dust particles. We discretise the grain size distribution in \( N_{\text{bin}} = 50 \) bins, where the grain size is sampled logarithmically between \( s_{\text{min}} \) and \( s_{\text{max}} \). The dust mass density can be written as:

\[
\rho_j \approx \frac{4}{3} \pi \rho_{s_{\text{max},j}}^3,
\]

where the subscript \( j \) refers to the \( j \)-th bin of dust particles. Here \( \rho_j \) is the mass density of the \( j \)-th bin, and \( s_{\text{max},j} \) is the maximum grain size of the \( j \)-th bin.

The steady version of the momentum equation for dust particles is:

\[
v_j \frac{dv_j}{dR} + \frac{GM_*}{R^2} - \frac{j^2}{R^3 + F_D/m_j} = 0,
\]

where we have assumed that dust is pressureless, and that the buoyancy term related to the gas pressure gradient is negligible (which is typically the case for astrophysical systems, see e.g. [Rice et al. 2006; Laibe & Price 2012]). The fluid quantities that do not show any subscript refer to gas properties, as in Section 3.2. The quantity \( m_j \) is the mass of the \( j \)-th dust particle. The last term \( F_D \) represents the aerodynamic force experienced by the dust particle. This force can assume different expressions, depending on the physical regime. If the size of the dust particle \( s \lesssim \lambda_{\text{mfp}} \), the mean-free path of gas molecules within the flow, the drag force reduces to the so-called [Epstein (1924)] drag. If the size of the particle is larger than the mean-free path, drag is a classical fluid [Stokes (1851)] drag. Within the winds addressed in this paper, \( \lambda_{\text{mfp}} > 10^4 \) cm (using \( \lambda_{\text{mfp}} \approx (\sigma_{\text{gas}} n)^{-1} \), where \( \sigma_{\text{gas}} \approx 10^{-16} \) cm\(^2\) is the geometrical cross-section of the gas molecules and \( n < 10^{11} \) cm\(^{-3}\)). For the dust particles considered here, \( s \ll \lambda_{\text{mfp}} \), and we can therefore use the Epstein limit to estimate the drag term (e.g. [Armitage 2010]).

\[
F_D = \frac{4\pi}{3} \rho s^2 v_{\text{th}} (v_j - v),
\]

where \( \rho = \mu m n \) is the gas mass density, and

\[
v_{\text{th}} = \sqrt{\frac{8k_B T}{\pi \mu m}}.
\]
is the mean thermal speed of the gas molecules.

If we rewrite equation (28) in the usual dimensionless form, and in the Epstein regime, we obtain:

\[
u_j = \frac{d\xi}{dt} = -\left[\beta \frac{\xi - 1}{\xi^3} + \tilde{J}_j g \sqrt{\gamma} (\nu_j - \tilde{u})\right],
\] (31)

where:

\[\tilde{J}_j = \sqrt{\frac{5}{\pi} \frac{\mu m_H c}{\rho \sigma_j}}\] (32)

and \(\nu_j = \nu_j/\nu_{c,\text{d}}\). For a given gaseous solution, we can obtain the velocity profile of the \(j\)-th bin of dust particles by integrating equation (31). We assume that dust particles are launched from the disc at the same speed of gas molecules, i.e., \(\nu_{j,d} = \nu_{d}\). Moreover, we require that the gas-to-dust ratio at the disc outer radius is 100, and this automatically sets the normalisation of the grain size distribution.

In order to obtain the maximum grain size entrained in the flow, we do not need to integrate equation (31) for every gaseous solution and every dust bin. If we consider the highly subsonic regime (\(\nu_j \sim 0\)) equation (31) becomes:

\[
u_j = -\beta \frac{\xi - 1}{\xi^3} + \tilde{J}_j g \sqrt{\gamma} \tilde{u} \equiv f_{\text{eff}},
\] (33)

where \(f_{\text{eff}}\) is the effective acceleration that a dust particle would feel if it were stationary. We define the stalling radius as the point at which a stationary dust grain would be in equilibrium, i.e., \(f_{\text{eff}} = 0\), which is different for each grain size. We have demonstrated by integration of equation (31) that dust particles within the flow indeed collect at their respective stalling radii (i.e. where \(f_{\text{eff}} = 0\)) where these exist (see Fig. 8). This can be explained by the fact that equation (31) resembles the equation of motion of an overdamped harmonic oscillator, where the system returns to equilibrium without oscillating and in an exponentially decaying fashion. As expected, the results show that the smaller grains are tightly coupled to the gas flow, and are easily dragged out to the critical radius. The largest grains are dragged to the stalling radius as defined above. Note that the stalling radius does not depend on the initial velocity, i.e. this result does not depend on the initial condition we have chosen for the velocity of the dust grains at \(R_d\).

This result confirms that in order to obtain the maximum grain size entrained in the flow \(s_{\text{entr}}\) we just need to solve equation \(f_{\text{eff}} = 0\), without obtaining the exact velocity profiles of every dust bin.

6 ITERATION PROCEDURE AND FINAL SOLUTIONS

In this section we summarise the iteration procedure we use to obtain the wind solutions by using all the ingredients reported in Section 4. All the results depend on the temperature estimates obtained with the PDR code in Section 5.

We initially set the main parameters of the system: the external FUV field \(G_{\text{FUV}}\), the disc’s outer radius \(R_o\), and the stellar mass \(M_*\). All the results shown in this paper have \(M_* = M_\odot\). We then set a critical temperature \(T_c\), which will be uniquely related to the pressure at the outer edge of the disc \(P_o\) of the final solutions. We then start the iteration procedure by assuming an initial \(\sigma_{\text{FUV}} = 8 \times 10^{-22} \text{cm}^{-2}\) for the \(s_{\text{max}} = 3.5 \mu\text{m}\) case and \(\sigma_{\text{FUV}} = 6 \times 10^{-23} \text{cm}^2\) when \(s_{\text{max}} = 1 \mu\text{m}\). We now list the following steps:

(i) we calculate the critical radius by using equations (12) and (13); (ii) we obtain all the boundary conditions of the gaseous flow at the critical radius, as explained in Section 4.2; (iii) we integrate the hydrodynamic equations from \(R_c\) inwards to the disc’s outer radius, with the method detailed in Section 4.3; (iv) we compute the maximum grain size \(s_{\text{entr}}\) entrained in the flow, by using equation (33); (v) we obtain the new cross section \(\sigma_{\text{FUV}}\); (vi) we go back to step (i), and we iterate the same procedure until we reach convergence on the cross section \(\sigma_{\text{FUV}}\).

As mentioned above, every solution selected via the input parameter \(T_c\) can be uniquely indicated by the gas pressure at the outer edge of the disc, which is a final output of our procedure. The boundary between the actual disc and the slow wind needs to be in pressure equilibrium (in principle there could be a contact discontinuity in both temperature and gas density). The pressure at the outer edge of the disc can be modelled by assuming simple prescriptions for the surface density and temperature profiles. For the latter, we use expression (22). For the former, we use the simple relation:

\[\Sigma(R) = \frac{M_d(2 - p)}{2\pi R_d^2} \left(\frac{R}{R_d}\right)^{-p},\] (34)

where \(M_d\) is the mass of the disc, and we set \(p = 1\) for the whole paper. A final pressure-balanced solution is thus selected by the mass of the disc.

The parameter space we explore is the following. We range over the disc outer radius between 20 and 250 AU, sampled every 10 AU. We explore three different values of external FUV field: 30, 300 and 3000 \(G_0\), and for each of these we explore a set of initial conditions specified by the parameter \(T_c\). The critical temperature is sampled every 2 K, and the explored range is shown in Fig. 4 for the different field values. Not all these initial conditions lead to a final solution, in particular there are cases where the equation defining the critical radius does not have a real solution. As already explained in the paper, we focus on two grain size distributions with \(q = 3.5\), where the maximum grain sizes are respectively 3.5 \(\mu\text{m}\) and 1 mm. The former leads to the same cross section used in the models by A04 when \(s_{\text{entr}} > 0.1 \mu\text{m}\), and this will allow us to compare our results with theirs in more detail.

7 RESULTS

We report here the global properties of the final solutions we have obtained. By construction, we obtain a class of transcritical solutions with a critical point in the heated flow. This implies that the velocity at the outer edge of the disc is subsonic, and thus all the solutions we obtain lie in the subcritical regime.

7.1 Profiles

The radial profiles of the gaseous quantities have characteristic features. Three examples are reported in Fig. 9, where we show the steady-state solutions for discs with \(R_d = 120\) AU, \(s_{\text{max}} = 1\) mm, and \(G_{\text{FUV}} = 30, 300\) and 3000 \(G_0\) (red, green and black lines). The solutions have been chosen such to have \(P_4 \sim 10^{-6}\) in cgs units. The dashed lines indicate the fluid quantities in the disc, parametrised by the temperature and surface density profiles given by relations (22) and (34). The wind solutions are shown out to the critical radius, which varies with the intensity of the external FUV field.
In the outer regions of the photoevaporative wind, the temperature increases with radius, as the flow becomes optically thicker to the external FUV radiation. Approaching the disc outer rim, the temperature drops drastically, as the gas becomes optically thick. In this radially narrow region, the gas is close to an isothermal hydrostatic solution, where the gas density $n$ grows exponentially, and the velocity drops accordingly. As we go inwards in the radial direction, very close to the disc outer edge, the velocity has a null gradient, which is expected for an isothermal Parker wind with the addition of the centrifugal term. Note that in all the solutions shown the optical depth at the critical point is less than unity (though only marginally so in the case $G_{\text{FUV}} = 3000 \, G_0$). This justifies a posteriori our assumption that the flow is roughly isothermal and at constant velocity outward of the critical point.

Other solutions have profiles that are optically thin to the FUV radiation along the whole flow. These solutions are characterised by a contact discontinuity in both temperature and density at the base of the flow (but the wind at $R_d$ is still in pressure equilibrium with the disc). An example is shown in Fig. 10. The density structure is close to being a power law profile (as in fig. 3 by A04), apart from the regions close to the disc edge, where the centrifugal term in the momentum equation becomes dominant. As we see in the next section, these solutions are characterised by a low disc mass and a tenuous mass loss.

### 7.2 Mass loss rates

For any given set of initial parameters $G_{\text{FUV}}$, $R_d$, and $T_0$ for which we obtain a solution, we can easily determine the mass loss rate from equation 2, this quantity is the most significant outcome of our model, since it determines whether the external photoevaporation mechanism is relevant for the global evolution of a protoplanetary disc, even when the environmental conditions are mild (e.g. $G_{\text{FUV}} = 30 \, G_0$). Note that all the mass loss rate estimates presented in this paper scale linearly with the assumed value of $F$ (see equation 2), i.e. depend on the scale height of the disc at its outer boundary $H_d$.

As an example, we condense most of the mass loss rates we obtain for both grain size distributions and $G_{\text{FUV}} = 30 \, G_0$ in Fig. 11. We show them with their dependence on the pressure at the
Figure 9. Profiles of the main thermo-hydrodynamical gaseous quantities for wind solutions between $R_d = 120$ (highlighted by the black vertical line) and $R_b$, with $s_{\text{max}} = 1$ mm. Colours indicate the three ambient field intensities analysed in the paper (red: $30 \, G_0$; green: $300 \, G_0$; black: $3000 \, G_0$). The solutions were chosen as to have $P_d \sim 10^{-6}$ in cgs units. The dashed lines represent the fluid quantities in the discs.

outer disc edge, as determined from the integration of the hydrodynamic equations. In the plots we focus on the range of pressure values that typify protoplanetary discs (which generally have mid-plane values of between $10^{-8} - 10^{-3}$ in cgs units depending on the disc mass, for $R > 20$ AU). The $x$-symbols indicate the actual outputs of the integration. Every line is associated with a disc outer radius, ranging from 70 to 250 AU. For the smallest disc sizes ($R_d < 70$ AU), the class of solutions is truncated at high $P_d$ values, and they do not appear on this plot. Finally, we struggle to obtain solutions in a physical range for the $s_{\text{max}} = 3.5 \, \mu m$ case, when $G_{\text{FUV}} = 3000 \, G_0$ and the discs are larger than $\sim 60$ AU. This limit is caused by our method of solution, since in these cases equation [9] for the critical radius does not have a real root.

Mass loss rates increase with disc outer radius, as one would
the two grain size distributions are comparable when the discs are small ($R_d \lesssim 100$ when $G_{FUV} = 30 G_0$, $R_d \lesssim 70$ when $G_{FUV} = 300 G_0$).

The fact that the gaseous flow is depleted of the larger grains has a relevant impact for the lowest mass loss rates, where $s_{\text{entr}} \lesssim \lambda = 0.1 \mu m$. There is in fact a strong correlation between the maximum grain size entrained in the flow, and the mass loss rate due to the photoevaporative wind. The top panels of Fig. 13 report such correlation for all the obtained solutions. As usual, every line represents a different disc size. The empirical understanding is straightforward: the more vigorous the wind, the larger are the grains that are dragged out with the gaseous flow. Obviously the maximum grain size entrained in the flow cannot be larger than the maximum grain size of the whole distribution, as well represented by the upper limit of $3.5 \mu m$ in the left panel of Fig. 13. If we neglect the centrifugal term in equation (28) (or in equation 13), and we set $f_{\text{eff}} = 0$ to determine $s_{\text{entr}}$, we obtain:

$$ s_{\text{entr}} \approx \frac{v_{\text{th}}}{GM} \frac{1}{4\pi \rho} \dot{M}, \quad (35) $$

where we have used the continuity equation 2 to extract $\dot{M}$. Since $v_{\text{th}}$ weakly depends on temperature only, which does not vary substantially among different solutions, the relation between $s_{\text{entr}}$ and $\dot{M}$ is roughly linear, as apparent in Fig. 13. The cross sections are significantly affected only at the low end of the mass loss rates (see bottom panel of Fig. 13), where the wind is so tenuous that $s_{\text{entr}} \ll \lambda = 0.1 \mu m$, and the cross section drops significantly.

For the $s_{\text{max}} = 3.5 \mu m$ case, the mass loss rates we obtain are generally lower (by a factor of $\sim 10$) than the ones derived by A04 (see their fig. 3), in the regions of parameter space that overlap, i.e. for small discs ($R_d \lesssim 60 \text{ AU}$). Since we have used a very similar cross section in this case, the difference cannot be due to a different penetrating depth. The factors that could be at the origin of such difference are at least two. The first one is the lower temperature in our models (see Section 8). In order to check whether the temperature has a significant effect in determining the mass loss rates, we have obtained other solutions with higher temperatures, of the same order as the ones presented in fig. 3 by A04 by using the prescription by Bakes & Tielens (1994) for the PAH photoelectric heating. The mass loss rates are not affected significantly, thus we can rule out that the lower mass loss rates in our study are due to the lower temperatures. The second factor, which is the most important one, is that in our non-isothermal treatment, the critical radius is always larger than the sonic radius by a factor of a few. Since the density scales very steeply with radius (more steeply than $R^{-2}$), a larger outer radius as boundary condition implies a much lower density $n_c$, in order to have a final pressure-balanced solution at $R_d$. This implies a lower mass loss rate (see equation 2).

8 DISCUSSION

The mass loss rates shown in Fig. 12 indicate that external photoevaporation can have a significant impact in the global evolution of protoplanetary discs. In particular, large discs ($R_d > 150 \text{ AU}$) show vigorous mass losses even for very low ambient fields ($G_{FUV} = 30 G_0$). Depending on the grain size distribution of the dusty material entrained in the flow, these discs can have mass loss rates as high as $\sim 10^{-7} \text{M}_\odot/\text{yr}$, if grain growth has been effective even at these outer regions of the disc. Thus, this effect needs to be considered when we model the evolution of protoplanetary discs.

---

**Figure 10.** Profiles between $R_d$ and $R_c$ of some relevant quantities for a disc with size $R_d = 40 \text{ AU}$, $G_{FUV} = 300 G_0$, $s_{\text{max}} = 1 \text{ mm}$ and $T_c = 228 \text{ K}$. This solution is associated with $M = 4.52 \times 10^{-9} M_\odot/\text{yr}$, $P_d = 4.93 \times 10^{-7}$ in cgs units, $n_d = 1.98 \times 10^{-7}$ particles per cc, and $s_{\text{entr}} \approx 1.7 \mu m$. Different lines indicate: black solid line: $n/n_d$; red dashed line: $T/(\text{K})$; blue dotted line: $v/c_{s,c}$; green dashed-dotted line: $\tau$. Intuitively expect, since the material at the outer rim is less embedded in the gravitational potential well of the central star. Moreover, the mass loss rates also increase with external FUV intensity, since higher fluxes heat the gas up to higher temperatures. In most of the parameter space shown in Fig. 11, there is a very weak dependence of the mass loss rates on the pressure in the outer disc (which is related, for canonical parameters, to the total disc mass). The only exception is in the case of low values of $P_d$. The reason is the following: a lower $\dot{M}$ corresponds to a roughly optically thin (and thus isothermal) flow (see e.g. Fig. 10). The flow solution is then just a centrifugally modified Parker wind solution. In this case the velocity structure is independent of the density normalisation. For a disc lying in this regime, with fixed $R_d$, the density normalisation at the base of the wind (and hence the mass loss rate) just scales linearly with the density in the disc. Hence (for a given disc temperature at $R_d$), $\dot{M}$ is linear with pressure.

Fig. 12 shows the same results reported in Fig. 11 for the three values of $G_{FUV} = 30$, 300 and 3000 $G_0$, where the mass loss rates are shown as a function of the disc outer radius, for different disc masses. The masses have been chosen such that $M_d = M_{d,0}(R_d/250 \text{ AU})^2$ in order to maintain the same surface density normalisation in the disc, where $M_{d,0}/M_\odot = 10^{-2}$ and $10^{-4}$ (solid, dashed and dashed-dotted lines, respectively). It is again apparent that the mass loss rates increase both with disc outer radius, and with the intensity of the impinging FUV radiation. As before we see a weak dependence on disc mass apart from where this is low, where the mass loss rate is nearly linear with disc mass at given $R_d$.

Another important feature is that the mass loss rates are very sensitive to the grain size distribution for large discs. When there is substantial grain growth, the cross section $\sigma_{\text{FUV}}$ decreases significantly (see Fig. 7), allowing a larger penetrating depth in the photoevaporative wind, and therefore a more significant mass loss rate. This is clearly shown in Fig. 12 where the mass loss rates from large discs are higher for the grain size distribution with larger maximum grain size, by roughly the ratio of the cross sections, as expected. However, the mass loss rates associated with
Clarke (2007), and later Anderson, Adams & Calvet (2013) (see also Mitchell & Stewart 2010), have shown that these photoevaporative winds affect disc evolution not on account of the mass lost in the flow, but by limiting the viscous spreading of the disc, and thus accelerating disc clearing. When the discs are large, the photoevaporative wind removes mass from the outer edge on a timescale shorter than the timescale with which the disc is able to replenish the mass in these regions. Thus the disc shrinks, until it reaches a radius where these two timescales are equal (see also A04 for a similar discussion). Another way of looking at the same mechanism is that when the mass flux at the base of the flow is higher than the one within the disc due to viscous spreading, the disc shrinks, whereas it expands as a standard viscous disc when the opposite happens. Anderson, Adams & Calvet (2013) already noticed that FUV external photoevaporation can have a significant impact in reducing the lifetime of protoplanetary discs for moderate external field intensities ($G_{\text{FUV}} = 300 G_0$). Both Clarke (2007) and Anderson, Adams & Calvet (2013) used the mass loss rates derived by A04. It will be worth investigating how the disc evolution will be affected by the lower mass loss rates we derived for compact discs, and the much higher ones when grain growth has occurred. The high mass loss rates we obtain in the latter case suggest that external photoevaporation might be a dominant mechanism in determining the outer radius of protoplanetary discs even in very mild environments, once large dust grains have formed in the discs’ outer regions.

In principle, in order to test this model in the low ambient field regime, we could follow two paths. The first one is statistical. For example, we could sample the outer radii of protoplanetary discs in different star forming regions, where the external FUV field can be considered quite uniform within the whole star forming region. Since Clarke (2007) showed that present disc sizes are very insensitive to the initial disc sizes when external photoevaporation is effective, in principle there should be a correlation between the present

---

**Figure 11.** Mass loss rates vs pressure at the edge of the disc for models with $s_{\text{max}} = 3.5 \mu m$ (left panel) and $s_{\text{max}} = 1 \text{ mm}$ (right panel), with an ambient FUV intensity of $30 G_0$. Every line represents a different outer radius $R_d$, sampled every 10 AU, from $R_d = 70$ AU (bottom yellow line) to $R_d = 250$ AU (top red line). The markers on top of the lines indicate the output of the actual integrations. Typical values of pressure at the outer edge of protoplanetary discs range between $10^{-8} - 10^{-3}$, in cgs units.

**Figure 12.** The dependence of mass loss rate on disc outer radius, for the two different grain size distributions with $s_{\text{max}} = 3.5 \mu m$ (left panel) and 1 mm (right panel). Different colours (red, green and black) indicate different external FUV field intensities, respectively $G_{\text{FUV}} = 30$, 300 and 3000 $G_0$. We show mass loss rates for disc masses $M_d = M_{d,0}(R_d/250 \text{ AU})^2$, where $M_{d,0}/M_d = 1$, $10^{-2}$ and $10^{-4}$ (solid, dashed and dashed-dotted lines, respectively).
average disc size, and the external FUV flux. Note however it is very challenging to obtain good estimates of disc sizes (although ALMA is now overcoming the problem), and even more it is very difficult to measure the FUV field in these regions. A prediction for the FUV intensity within the cluster can be estimated by integrating the contribution from all the known radiation sources, even though the 3D structure of these regions is still not known. Another theoretical uncertainty is that the expected outer radii strongly depend on the assumed viscosity in the disc, and on its initial mass. Note that Anderson, Adams & Calvet (2013) have already conducted a similar exploratory study for the ONC, where the FUV radiation within the cluster can be estimated well, since it is dominated by the radiation of the massive $\theta$C star.

A second approach is to observe this photoevaporative flow directly in discs where we know that the external radiation is mild, since there are no close energetic sources. Examination of Fig. 9 suggests that the surface densities in the flow can be high enough ($\sim 10^{-3} - 10^{-2}$ $g$/cm$^2$) to be detectable in molecular line emission (e.g. $^{13}$CO) with reasonable sensitivities. The outer regions are typified by a steep cliff in surface density surrounded by a gently sloping plateau of low density gas. The same regions would also be highly depleted in large grains ($s_{\text{entr}} \lesssim 1 \mu$m), and thus the disc outer radius estimated from dust continuum emission will be smaller than the one traced by molecular line emission. A good example of this feature is the huge 114–426 protoplanetary disc observed in silhouette by HST in Orion (Ricci, Robberto & Soderblom 2008), where the outer regions associated with a photoevaporative flow (e.g. Miotello et al. 2012) are not observed in dust continuum emission at submm wavelengths (Mann et al. 2014, Bally et al. 2015), and present hints of radial gradient in the maximum grain size entrained in the flow (Miotello et al. 2012). Note however in this case the disc is so large ($R_d \sim 1000$ AU) that it is expected to lie in the supercritical regime of FUV photoevaporation.

The presence of these dust depleted structures in the outskirts of protoplanetary discs can be interpreted as the outcome of other physical processes, such as the radial drift of dust particles in the absence of a wind (Birnstiel & Andrews 2014). However, discs affected by external photoevaporation will present other two features that are not compatible with the pure radial drift scenario. The first one is a positive temperature gradient in the regions associated with the flow. The second signature is kinematic: since the specific angular momentum in the flow equals the specific angular momentum at $R_d$, the angular velocity of the flow will scale as $R^{-2}$, instead of the typical Keplerian $R^{-3/2}$. The observability of this feature favours small discs, where the absolute deviation from a Keplerian

Figure 13. Top panels: maximum grain size entrained in the photoevaporative wind, in the case of $G_{\text{FUV}} = 30 G_0$. As usual, every line represents a different disc size. There is a strong correlation between $s_{\text{entr}}$ and the mass loss rates: the more vigorous is the flow, the larger the entrained maximum grains are. Bottom panels: cross sections of the same solutions reported in the top panels. Note the different range on the y-axis. As expected, the cross sections become very sensitive to $s_{\text{entr}}$, when $s_{\text{entr}} \lesssim \lambda = 0.1 \mu$m, as shown in Fig. 7.
9 CONCLUSIONS

In this paper we present new mass loss rates of externally photoevaporated discs covering a large parameter space. In particular, we are able to self-consistently solve the hydrodynamical equations of the photoevaporative winds for large discs (up to $R_d = 250$ AU) and low FUV fluxes (down to $G_{FUV} = 30 G_0$), where previous studies have been unable to obtain numerical solutions. We have shown that the method of solution can significantly affect the final estimates of the mass loss rates. More specifically, by properly treating the non-isothermal nature of the flow, we obtain lower mass loss rates than had been previously determined for an ISM-like dust component of the disc.

We have shown that the grain size distribution of the dust component of the disc has a significant effect on the mass loss rate. When grain growth has occurred in the midplane of the disc, out to its outer radius, the mass loss is remarkably more vigorous, mostly because of the consequent reduction of the cross section of dust particles at FUV wavelengths. Note that we have assumed that grain growth does not affect the PAH abundance, where PAHs are the most significant heating source at almost all gas densities and optical depths considered here. Thus our assumption implies that the total gas heating is not significantly affected by grain growth (see Sections 3.2 - 3.3). For a moderate maximum size of the dust grain size distribution ($s_{max} = 1$ mm), and a standard dust to gas ratio of 0.01, we obtain a mass loss rate of $\dot{M} > 10^{-8} M_\odot/yr$ when $R_d > 150$ AU and $G_{FUV} = 30 G_0$, and $M_d \gtrsim 10^{-3} M_\odot$. For the same parameters the mass loss rate can be as high as $10^{-7} M_\odot/yr$ when $R_d \sim 250$ AU. These high mass loss rates are expected to significantly affect the global evolution of protoplanetary discs. Our results indicate that even very mild environments can lead to significant truncation of the disc outer radius, especially when grain growth is effective. Such truncation is also expected to yield an acceleration of disc clearing. We thus predict that external photoevaporation is a more significant mechanism leading to disc clearing than previously considered. For such low values of the external field, future disc evolution models should include photoevaporation caused by both the external FUV field and the FUV flux from the central star (Gorti & Hollenbach 2009)(Gorti, Hollenbach & Dullemond 2015), as suggested by Anderson, Adams & Calvet (2013).

We have suggested observable characteristic features that can probe a currently photoevaporating disc. In particular, our results show that photoevaporative winds are highly dust depleted, and that their surface densities can be observed in molecular line emission with present facilities (ALMA in particular). Strong evidence of ongoing external photoevaporation in this mild regime is a positive thermal radial gradient in the flow region, which can be probed by spatially resolved line ratios of different rovibrational transitions, and a non-Keplerian rotation curve that can be obtained via line kinematics.

Finally we emphasise that the present work is restricted to solar mass stars. As noted by AD04 we expect the effect of external photoevaporation to be yet more significant in the case of lower mass stars since the gravitational well is shallower.

ACKNOWLEDGEMENTS

We thank the anonymous referee whose comments helped improving the quality of the paper and the description of the PDR modeling. We are grateful to Mark Wyatt for providing us the code to compute the dust opacities. We thank James Owen, Serena Viti, Richard Alexander, Grant Kennedy and Ewine van Dishoeck for stimulating discussion. We also thank Benedetta Caggioni for helping with Fig. 7. SF thanks the Science and Technology Facility Council and the Isaac Newton Trust for the award of a studentship. This work has been supported by the DISCSIM project, grant agreement 341137 funded by the European Research Council under ERC-2013-ADG. The work of TGB was funded by STFC grant ST/J001511. All the figures were generated with the PYTHON-based package MATPLOTLIB (Hunter 2007).
