ABSTRACT

Estimates for the nonlinear $\alpha$ effect in helical turbulence with an applied magnetic field are presented using two different approaches: the imposed-field method where the electromagnetic force owing to the applied field is used, and the test-field method where separate evolution equations are solved for a set of different test fields. Both approaches agree for stronger fields, but there are apparent discrepancies for weaker fields that can be explained by the influence of dynamo-generated magnetic fields on the scale of the domain that are referred to as meso-scale magnetic fields. Examples are discussed where these meso-scale fields can lead to both drastically overestimated and underestimated values of $\alpha$ compared with the kinematic case. It is demonstrated that the kinematic value can be recovered by resetting the fluctuating magnetic field to zero in regular time intervals. It is concluded that this is the preferred technique both for the imposed-field and the test-field methods.

Key words: magnetic fields — MHD — hydrodynamics — turbulence

1 INTRODUCTION

The $\alpha$ effect is commonly used to describe the evolution of the large-scale magnetic field in hydromagnetic dynamos (Moffatt 1978, Parker 1979, Krause & Rädler 1980). However, the $\alpha$ effect is not the only known mechanism for explaining the generation of large-scale magnetic fields. Two more effects have been discussed in cases when there is shear in the system: the incoherent $\alpha$–shear dynamo (Vishniac & Brandenburg 1997; Sokolov 1997; Silant'ev 2000; Proctor 2007) and the shear–current effect (Rogachevskii & Kleeorin 2003, 2004). In order to provide some understanding of the magnetic field generation in astrophysical bodies such as the Sun or the Galaxy, or at least in numerical simulations of these systems, it is of interest to be able to identify the underlying mechanism.

Astrophysical dynamos are usually confined to finite domains harboring turbulent fluid motion. Both the Sun and the Galaxy are gravitationally stratified and rotating, which makes the turbulence non-mirror symmetric, thus leading to an $\alpha$ effect. In addition, the rotation is nonuniform, which leads to a strong amplification of the magnetic field in the toroidal direction, as well as other effects such as those mentioned above. Instead of simulating such systems with all their ingredients, it is useful to simplify the setup by restricting oneself to Cartesian domains that can be thought to represent a part of the full domain. At low magnetic Reynolds numbers, i.e. when the effects of induction are comparable to those of magnetic diffusion, the $\alpha$ effect can clearly be identified in simulations of convection in Cartesian domains; see Brandenburg et al. (1990). Here, $\alpha$ has been determined by applying a uniform magnetic field across the simulation domain and measuring the resulting electromagnetic force. This method is referred to as the imposed-field method. However, in subsequent years simulations at larger magnetic Reynolds numbers have revealed problems in that the resulting $\alpha$ becomes smaller and strongly fluctuating in time. This was first found in simulations where the turbulence is caused by an externally imposed body force (Cattaneo & Hughes 1996), but it was later also found for convection (Cattaneo & Hughes 2000). This suggested that the mean-field approach may be seriously flawed (Cattaneo & Hughes 2009).

Meanwhile, there have been a number of simulations of convection where large-scale magnetic fields are being generated. Such systems include not only simulations in spherical shells (Brown et al. 2006, Brown et al. 2007), but also in Cartesian domains (Käpylä et al. 2008, 2009, Hughes & Proctor 2009). However, the absence of a significant $\alpha$ effect in some of these simulations led Hughes & Proctor (2009) to the conclusion that such magnetic fields can only be explained by other mechanisms such as the incoherent $\alpha$–shear dynamo or the shear–current effect. Such an explanation seems to be in conflict with earlier claims of a finite $\alpha$ effect as determined by the test-field method of (Schrinner et al. 2005, 2007), and in particular with recent results for convection (Käpylä et al. 2009b). The purpose of the present paper is therefore to discuss possible reasons for conflicting results that are based on different methods. The idea is to compare measurements of the $\alpha$ effect using both the imposed-field method and the test-field method. We consider here the case of helically forced turbulence in a triply-periodic domain. This case is believed to be well understood. We expect $\alpha$ to be catastrophically quenched, i.e. $\alpha$ is suppressed for field strengths exceeding the Zeldovich (1957) value of $R_m^{-1/2}B_{eq}$, where $B_{eq}$ is the equipartition field.
2 HELICAL TURBULENCE AND α EFFECT

2.1 Forced turbulence simulations

Throughout this paper we consider hydromagnetic turbulence in the presence of a mean magnetic field \( B_0 \) using triply-periodic boundary conditions. The total magnetic field is written as \( B = B_0 + \nabla \times A \), where \( A \) is the magnetic vector potential. We employ an isothermal equation of state where the pressure is proportional to the density, \( p = \rho c_s^2 \), with \( c_s \) being the isothermal sound speed. The governing evolution equations for logarithmic density \( \ln \rho \), velocity \( U \), together with \( A \), are given by

\[
\frac{D \ln \rho}{Dt} = -\nabla \cdot U, \tag{1}
\]

\[
\frac{D U}{Dt} = J \times (B_0 + B)/\rho + f + F_{\text{visc}} - c_s^2 \nabla \ln \rho, \tag{2}
\]

\[
\partial A \cdot U = U \times (B_0 + B) + \eta \nabla^2 A, \tag{3}
\]

where \( B_0 + B \) is the total magnetic field, but since \( B_0 = 0 \) it does not enter in the mean current density, which is given by \( J = \nabla \times B/\mu_0 \), where \( \mu_0 \) is the vacuum permeability. Furthermore, \( D/Dt = \partial/\partial t + U \cdot \nabla \) is the advective derivative, \( F_{\text{visc}} = \rho^{-1} \nabla \cdot 2 \nu \mathbf{S} \) is the viscous force, \( \nu \) is the kinematic viscosity, \( S_{ij} = \frac{1}{2} (U_{ij} + U_{ji}) - \frac{1}{3} \delta_{ij} \nabla \cdot U \) is the traceless rate of strain tensor, and \( f \) is a random forcing function consisting of plane transversal waves with random wavevectors \( k \) such that \( |k| \) lies in a band around a given forcing wavenumber \( k_1 \). The vector \( k \) changes randomly from one timestep to the next. This method is described for example in [Haugen et al. 2004]. The forcing amplitude is chosen so that the Mach number \( Ma = u_{rms}/c_s \) is about 0.1.

We consider a domain of size \( L_x \times L_y \times L_z \). We use \( L_x = L_y = L_z = 2\pi/k_1 \) in all cases. Our model is characterized by the choice of magnetic Reynolds and Prandtl numbers, defined here via

\[
R_m = u_{rms}/k_1, \quad P_m = \nu/\eta. \tag{4}
\]

We start the simulations with zero initial magnetic field, so the field is entirely produced by the imposed field. The value of the magnetic field will be expressed in units of the equipartition value

\[
B_{eq} = (\mu_0 u_{rms}^2)^{1/2}. \tag{5}
\]

We consider values of \( B_0/B_{eq} \) from 0.06 to 20 along with a magnetic Reynolds number of about 26, adequate to support dynamo action.

2.2 α from the imposed-field method

The present simulations allow us to determine directly the \( \alpha \) effect under the assumption that the relevant mean field is given by volume averages, denoted here by angular brackets. Given that the magnetic field is written as \( B = \nabla \times A \) where \( A \) is also triply periodic, we have \( \langle B \rangle = 0 \). We can determine the volume-averaged electromotive force,

\[
\langle \mathbf{E} \rangle = \langle \mathbf{E} \rangle(t) \equiv \langle \mathbf{u} \times \mathbf{b} \rangle, \tag{6}
\]

where \( \mathbf{u} = U - \langle U \rangle \) and \( \mathbf{b} = B \) are the fluctuating components of velocity and magnetic field, and \( \langle B \rangle = \langle \nabla \times A \rangle = 0 \).

For mean fields defined as volume averages, and because of periodic boundary conditions, we have \( \langle J \rangle = 0 \). Under isotropic conditions there is therefore only the \( \alpha \) effect connecting \( \langle \mathbf{E} \rangle \) with \( B_0 \) via \( \langle \mathbf{E} \rangle \equiv \alpha_{\text{imp}} B_0 \), so

\[
\alpha_{\text{imp}} = \frac{\langle \mathbf{E} \rangle}{B_0}. \tag{7}
\]

In all cases reported below we assume \( B_0 = (B_0, 0, 0) \). Note that \( \nabla \times \langle \mathbf{E} \rangle = 0 \) and therefore our time-constant imposed field is self-consistent.

2.3 α from the test-field method

A favored method of determining the full \( \alpha_{ij} \) tensor is by using the test-field method [Schrinner, 2005, 2007], where one solves, in addition to equations (1)-(4), a set of equations. In the special case of volume averages this set of equations simplifies to

\[
\frac{\partial \langle \mathbf{q} \rangle}{\partial t} = \mathbf{U} \times \mathbf{B}^0 + \mathbf{u} \times (\mathbf{B}_0 + \mathbf{B}^0) + \mathbf{u} \times \mathbf{b}^0 - \mathbf{u} \times \mathbf{b}^0 + \eta \nabla^2 \mathbf{a}^0, \tag{8}
\]

where \( \mathbf{b}^0 = \nabla \times \alpha^0 \) with \( q = 1 \) or \( 2 \) denotes the response to each of the two test fields \( \mathbf{B}^0 \). Throughout this paper, overbars denote planar averages. Later we consider arbitrary planar averages and denote their normals by superscripts, but here we restrict ourselves to \( x \) \( y \) averages. We use two different constant test fields,

\[
\mathbf{B}^1 = (B, 0, 0), \quad \mathbf{B}^2 = (0, B, 0), \tag{9}
\]

where \( \mathbf{B} = \text{const} \) is the magnitude of the test field, but its actual value is of no direct significance, because the \( B \) factor cancels in the calculation of \( \alpha \).

However, given that the test-field equations are linear in \( \mathbf{b}^0 \), this field can grow exponentially due to dynamo action. When \( |\mathbf{b}| \) becomes larger than about 20 times the value of \( \mathbf{B} \), the determination of \( \alpha \) becomes increasingly inaccurate, so it is advisable to reset \( \mathbf{b}^0 \) to zero in regular intervals [Sur et al. 2008]. We calculate the corresponding values of the electromotive force \( \langle \mathbf{E} \rangle^q = \langle \mathbf{u} \times \mathbf{b}^0 \rangle \) to determine the components

\[
\alpha_{ij} = \langle \mathbf{E} \rangle^q_i/B. \tag{10}
\]

This corresponds to the special case \( k = 0 \) when considering sinusoidal and cosinusoidal test functions described elsewhere [Brandenburg, Rädler & Schrinner, 2008].

Even though the test-field equations themselves are linear, the flow field is affected by the actual magnetic field (which is different from the test field), so the resulting \( \alpha \) tensor is being affected (“quenched”) by the magnetic field. This was successfully demonstrated in [Brandenburg et al., 2008b], where \( \alpha_{ij} \) takes the form

\[
\alpha_{ij} = \alpha_1 \delta_{ij} + \alpha_2 \tilde{B}_i \tilde{B}_j, \tag{11}
\]

Here \( \mathbf{B} = \mathbf{B}/|\mathbf{B}| \) is the unit vector of the relevant mean magnetic field. In the induction equation the \( \alpha \) effect occurs only in the combination

© 0000 RAS, MNRAS 000, 000–000
\[ \alpha_{ij} \overline{B}_j = (\alpha_1 + \alpha_2) \overline{B}_i, \] 

(12)

and this is also what is determined by the imposed-field method, but it is different from the mean values of the components of the \( \alpha_{ij} \) tensor. On the other hand, in the case of a passive vector field it is the mean components of \( \alpha_1 \) rather than the components of \( \alpha_{ij} \overline{B}_j \), that are of immediate importance (Tilgner & Brandenburg 2008).

2.4 \( \alpha \) in the presence of meso-scale fields

The relevant mean field may not just be the imposed field with wavenumber \( k = 0 \), but it may well be a field with wavenumber \( k = k_1 \). Such a field would vanish under volume averaging, but it would still produce finite values of \( \langle \overline{B}_i \overline{B}_j \rangle \). For the diagonal components of \( \langle \alpha_{ij} \rangle \) we can write

\[ \langle \alpha_{xx} \rangle = \alpha_1 + \epsilon_x \alpha_2, \quad \langle \alpha_{yy} \rangle = \alpha_1 + \epsilon_y \alpha_2, \]

(13)

where the factors

\[ \epsilon_x = \langle \overline{B}_x^2 \rangle, \quad \epsilon_y = \langle \overline{B}_y^2 \rangle, \]

(14)

quantify the weight of the \( \alpha_2 \) term. For a purely uniform field pointing in the \( x \) direction we have \( \epsilon_x = 1 \) and \( \epsilon_y = 0 \), while for a Beltrami field of the form \( \overline{B} = (\cos k z, \sin k z, 0) \) we have \( \epsilon_x = \epsilon_y = 1/2 \).

In practice we will have a mixture between the imposed field (below sometimes referred to as large-scale field) and a dynamo-generated magnetic field with typical wavenumber \( k = k_1 \) (below sometimes referred to as meso-scale magnetic field). The solution to the test-field equations, \( b^i \), can also develop meso-scale fields with wavevectors in the \( x \) or \( y \) directions, but not in the \( z \) direction, because that component is removed by the term \( \overline{u} \times \overline{B} \) in equation (8). Table 1 highlights the difference between imposed, meso-scale, and test fields. We denote the ratio of the strengths of imposed and meso-scale fields as \( \beta = B_0/B_1 \) and distinguish three (and later four) different cases, depending on the direction of the wavevector of the Beltrami field.

The first case is referred to as the \( X \) branch, because the wavevector of the Beltrami field points in the \( x \) direction. To calculate \( \epsilon_x \) there is, in addition to the imposed field \( B_0 \), a Beltrami field \( B_1(0, \cos k z, \sin k z) \), which does not have a component in the \( x \) direction. Thus, \( B_x = B_0 \), and since \( \overline{B} = (B_0, B_1 \cos k z, B_1 \sin k z) \), we have \( B_x^2 = B_0^2 + B_1^2 \), so \( \epsilon_x = \beta^2 = B_0^2/(B_0^2 + B_1^2) \). Likewise, with \( B_y = B_1 \cos k z \) we find for the volume average or, in this case, the \( x \) average \( B_x^2 \) to be \( B_0^2/2 \), so \( \epsilon_y = 1/[2(1 + \beta^2)] \).

The next case is referred to as the \( Y \) branch, because the wavevector of the Beltrami field points in the \( y \) direction. Thus, we have \( B = (B_0 + B_1 \sin k y, 0, B_1 \cos k y) \), so \( B_x^2 = B_0^2 + 2B_0B_1 \sin k y + B_1^2 \). This is no longer independent of position, so the volume average or, in this case, the \( y \) average has to be obtained by integration. Thus, we write \( \epsilon_y = I_1(\beta) \) where we have defined

\[ I_1(\beta) = \int_0^{2\pi} \frac{(\beta + \sin \theta)^2}{\beta^2 + 2 \beta^2 \sin \theta + 1} d\theta = \begin{cases} 1/2 & \beta^2 \leq 1, \\ 1 - 1/2 \beta^2 & \beta^2 > 1, \end{cases} \]

where \( \theta = k y \) has been introduced as dummy variable. Since \( B_y = 0 \) in this case, we have \( \epsilon_y = 0 \).

Finally, for the \( Z \) branch, where the wavevector of the Beltrami field points in the \( z \) direction, we have \( \overline{B} = (B_0 + B_1 \cos k z, B_1 \sin k z, 0) \), we find \( \epsilon_x = I_1(\beta) \) and \( \epsilon_y = I_2(\beta) \) with

\[ I_2(\beta) = \int_0^{2\pi} \frac{\cos^2 \theta}{\beta^2 + 2 \cos \theta + 1} \frac{d\theta}{2\pi} = \begin{cases} I_0(\beta)/\beta^2 & \beta^2 < 1, \\ I_0(\beta)/\beta^2 & \beta^2 > 1, \end{cases} \]

where \( I_0(\beta) = (1 + \beta^2)/[2(1 - \beta^2)] \) and \( \theta = k z \) has been used as a dummy variable. A graphical representation of the integrals is given in Fig. 1 and a summary of the expressions for \( \epsilon_x(\beta) \) and \( \epsilon_y(\beta) \) as well as \( \epsilon_x(0) \) and \( \epsilon_y(0) \) for the \( X \), \( Y \), and \( Z \) branches is given in Table 2. The singularity in \( I_0(\beta) \) could potentially affect \( \alpha_{yy} \). However, the results shown below show that, at least for stronger fields, \( \alpha_{yy} \) goes to zero near the singularity of \( I_0(\beta) \) such that \( \alpha_{yy} \) remains finite.

3 RESULTS

We have performed simulations for values of \( B_0 \) in the range \( 0.06 \leq R_m^{0.1} B_0/B_m \leq 20 \) for \( R_m \approx 26 \) and \( P_m = 1 \). In all cases we use \( k_1/k_1 = 3 \), which is big enough to allow a meso-scale magnetic field of wavenumber \( k_1 \) to develop within the domain; see Fig. 2. We did not initially anticipate the importance of the meso-scale fields. Different runs were found to exhibit rather different behavior which turned out to be related to their random positioning on different branches. We used the existing results from different branches as initial conditions for neighboring values of \( B_0 \).
3.1 Different branches

The resulting values of $\alpha$ are shown in Fig. 3. For strong imposed magnetic fields, $R_m B^2_0/B^2_{eq} > 1$, the resulting dependence of $\alpha$ on $B_0$ obeys the standard catastrophic quenching formula for the case of a uniform magnetic field (Vainshtein & Cattaneo 1992),

$$\alpha_{fit} = \frac{\alpha_0}{1 + R_m B^2_0/B^2_{eq}} \quad \text{(for } B = B_0 = \text{const only)},$$

where $\alpha_0 = -\frac{1}{3} u_{rms}$ is the relevant kinematic reference value for fully helical turbulence with negative helicity and $R_m > 1$ (Sur et al. 2008). We treat $R_m$ as an empirical fit parameter that is proportional to $R_m$ and find that $R_m/R_m \approx 0.4$ gives a reasonably good fit; see the dash-dotted line in Fig. 3. The existence of such an empirical factor might be related to fact that the relevant quantity could be the width of the magnetic inertial range, and that this is not precisely equal to $R_m$. For $R_m B^2_0/B^2_{eq} > 1$, a similar result is also reproduced using the test-field method, although $\alpha_{xx}$ is typically somewhat larger than $\alpha_{imp}$.

For weak imposed magnetic fields, $R_m B^2_0/B^2_{eq} < 1$, apparent discrepancies are found between the imposed-field method and the test-field method. In fact, in the graphical representation in Fig. 3, the results can be subdivided into four different branches that we refer to as branches X, Y, Z, and YZ. These names have to do with the orientation of a dynamo-generated magnetic field. These dynamo-generated magnetic fields take the form of Beltrami fields that vary in the $x$, $y$, and $z$ directions for branches X, Y, and Z, while for branch YZ the field varies both in the $y$ and $z$ directions. Earlier work without imposed fields has shown that branch YZ can be accessed during intermediate times during the saturation of the dynamo, but it is not one of the ultimate stable branches X, Y, or Z.

Branches Y and Z show the sudden onset of suppression of $\alpha_{imp}$ for weak magnetic fields. This has to do with the fact that for weak imposed magnetic fields a dynamo-generated field of Beltrami type is being generated. Such fields quench the $\alpha$ effect, even though they do not contribute to the volume-averaged mean field. On branch YZ the $\alpha$ effect is only weakly suppressed, while on branch X the imposed-field $\alpha_{imp}$ increases with decreasing values of $B_0$.

In this paper, error bars are estimated from the averages obtained from any of three equally long subsections of the full time series. The error bars are comparable with the typical scatter of the data points, but they are not shown because they would make the figure harder to read. Note that the results in this section consider saturated fields. The opposite case will be considered in Sect. 4.

Figure 2. Visualization of $B_z$ on the periphery of the computational domain for the X branch and $B_x$ for the Y, Z, and YZ branches. The coordinate directions are indicated on the first panel.

Figure 3. Volume-averaged values of $\alpha_{imp}$, $\alpha_{xx}$, and $\alpha_{yy}$. A tilde indicates that the values are normalized by $\alpha_0$, i.e. $\tilde{\alpha}_{imp} = \alpha_{imp}/\alpha_0$ (solid line), $\tilde{\alpha}_{xx} = (\alpha_{xx})/\alpha_0$ (dashed line), $\tilde{\alpha}_{yy} = (\alpha_{yy})/\alpha_0$ (dotted line), and $\tilde{\alpha}_{fit} = \alpha_{fit}/\alpha_0$ (thick gray line, but only shown in the second panel). The two open symbols in the top panel indicate that the values of $\alpha_{xx}/\alpha_0$ are negative.
The \( \alpha \) effect with imposed magnetic fields

Figure 4. Root-mean-square values of the mean magnetic fields as functions of the imposed field for turbulence with \( R_m = 26 \) for the X, Y, Z, and YZ branches in the same order as in Fig. 3. Diamonds, triangles, and squares denote \( \overline{B}(x) \), \( \overline{B}(y) \), and \( \overline{B}(z) \), respectively.

The test-field method reveals that on branches X, Y, and YZ the \( \alpha_{yy} \) component is nearly independent of \( B_0 \), and always larger than the \( \alpha_{xx} \) component. However, on branch Z and for \( R_m B_0^2 / B_{eq}^2 < 1 \) we find that \( \alpha_{xx} = \alpha_{yy} \) and only weakly suppressed.

A comment regarding the discontinuities in Fig. 3 near \( R_m B_0^2 / B_{eq}^2 = 1 \) is here in order. The systems considered here are in saturated states. To the left of the discontinuities the system has a saturated meso-scale dynamo, while to the right there is none. Intermediate states are simply not possible. Hence, the discontinuities are caused by the effects of the meso-scale magnetic fields on \( u_{rms} \) and thus on \( R_m \).

3.2 Relation to \( \alpha_1 \) and \( \alpha_2 \)

In the following we will try to interpret the results presented above in terms of equation (11) and determine \( \alpha_1 \) and \( \alpha_2 \) for the different branches. For small values of \( B_0 \), a magnetic field with \( k = k_1 \) and hence a finite planar average can develop. Compared with the large-scale field \( B_0 \), we refer to this dynamo-generated field as meso-scale magnetic field. As demonstrated in [Brandenburg 2001], three types of such mean fields are possible in the final saturated state. These fields correspond to Beltrami fields of the form

\[
\begin{align*}
\overline{B}(x) &= \left( \begin{array}{c}
0 \\
c_x \\
s_z 
end{array} \right), & \overline{B}(y) &= \left( \begin{array}{c}
s_y \\
0 \\
c_y 
end{array} \right), & \overline{B}(z) &= \left( \begin{array}{c}
c_z \\
s_x \\
0 
end{array} \right),
\end{align*}
\]

(16)

where \( c_\xi = \cos(k_1 \xi + \phi) \) and \( s_\xi = \sin(k_1 \xi + \phi) \) denote cosine and sine functions as functions of \( \xi = x, y, \) or \( z \), with an arbitrary phase shift \( \phi \). The precise value of \( B_1 \) emerges as a result of the simulation, but based on simulations in a periodic domain [Brandenburg 2001] we know that \( B_1 / B_{eq} \) should be about \( (k_1 / k_1)^{1/2} \) times the equipartition value. This is also confirmed by the present calculations.

Unlike the case considered by [Brandenburg et al. 2008], here the test field has \( k = 0 \), and there is no relative phase to be considered.
Let us now discuss separately the different branches. As can be seen from Fig. 3, the weak-field regime is characterized by the presence of meso-scale magnetic fields that vary either in the $x$ direction (the X branch), the $y$ direction (Y branch), the $z$ direction (Z branch), or in both the $y$ and $z$ directions (YZ branch). In order to get some idea about the values $\alpha_1$ and $\alpha_2$ on the various branches, we consider two limiting cases. For strong imposed fields, $\beta \to \infty$, the results lie formally on the YZ branch. Furthermore, $\langle \mathbf{B}_0 \mathbf{B}_1 \rangle$ will be dominated only by the uniform field in the $x$ direction, so we have $\epsilon_x = 1$ and $\epsilon_y = 0$; see Sect. 2.3. This means that $\alpha_{\text{imp}} = \tilde{\alpha}_xx = \tilde{\alpha}_1 + \tilde{\alpha}_2$ and $\tilde{\alpha}_{\text{yy}} = \tilde{\alpha}_1$, so we can calculate

\[ \tilde{\alpha}_1 = \tilde{\alpha}_{\text{yy}}, \quad \tilde{\alpha}_2 = \tilde{\alpha}_{\text{imp}} - \tilde{\alpha}_{\text{yy}}, \]  

(17)

where a tilde indicates normalization by $\alpha_0$. For weak imposed fields, $\beta \to 0$, we can calculate $\tilde{\alpha}_1$ and $\tilde{\alpha}_2$ on the X branch by using the relations

\[ \tilde{\alpha}_{xx} = \tilde{\alpha}_1, \]  

(18)

\[ \tilde{\alpha}_{yy} = \tilde{\alpha}_1 + \frac{1}{2} \tilde{\alpha}_2, \]  

(19)

\[ \tilde{\alpha}_{\text{imp}} = \tilde{\alpha}_1 + \tilde{\alpha}_2. \]  

(20)

However, on the X branch $\tilde{\alpha}_{xx}$ is ill-determined, as seen in Fig. 3 and discussed in Sect. 3.1 below. Therefore we use only equations (19) and (20) to calculate

\[ \tilde{\alpha}_1 = 2 \tilde{\alpha}_{yy} - \tilde{\alpha}_{\text{imp}}, \quad \tilde{\alpha}_2 = 2 \tilde{\alpha}_{\text{imp}} - 2 \tilde{\alpha}_{yy}. \]  

(21)

For the Y, Z, and YZ branches, on the other hand, these relations have to be substituted by

\[ \tilde{\alpha}_1 = 2 \tilde{\alpha}_{xx} - \tilde{\alpha}_{\text{imp}}, \quad \tilde{\alpha}_2 = 2 \tilde{\alpha}_{\text{imp}} - 2 \tilde{\alpha}_{xx}. \]  

(22)

The resulting values of $\tilde{\alpha}_1$ and $\tilde{\alpha}_2$ are plotted in Fig. 5 for each of the four branches. On the Y branch one can, as a test, also use the independent relation $\tilde{\alpha}_1 = \tilde{\alpha}_{yy}$. The resulting values are about 50% larger than the values shown in Fig. 5 suggesting that there could be additional contributions in the simplified relation $\tilde{\alpha}_{yy} = \tilde{\alpha}_1$. On the Z branch, of course, $\tilde{\alpha}_{xx} = \tilde{\alpha}_{yy}$, so here too we have to use the equations (22).

In all cases we find that $\tilde{\alpha}$ is quenched by $\tilde{\alpha}_1$ and $\tilde{\alpha}_2$ having opposite signs and their moduli approaching each other. This is particularly clear in the case of strong fields where $\tilde{\alpha}_1$ and $-\tilde{\alpha}_2$ become indistinguishable, while each of them is still increasing. We note that the turbulence itself is not strongly affected (Brandenburg & Subramanian 2005a). On the Y and Z branches both $\tilde{\alpha}_1$ and $\tilde{\alpha}_2$ are of order unity, but on the X branch they can reach rather large values when the imposed field is weak. The behavior on the YZ branch is somewhat unsystematic, suggesting that this branch is really just the result of a long-term transient, as was already found in the absence of an imposed field (Brandenburg 2001). However, we decided not to discard this branch, because it is likely that transient solutions on this branch may become even more long-lived as the magnetic Reynolds number is increased further.

3.3 Enhancement of $\alpha_{\text{imp}}$ in the field-aligned case

The suppression of $\alpha = \alpha_1 + \alpha_2$ by the magnetic field is not surprising. What is unexpected, however, is the dramatic enhancement of both $\alpha_1$ and $-\alpha_2$ for weak imposed fields and equipartition-strength meso-scale fields that vary in the $x$ direction (the field-aligned case or X branch). In this case the interactions of the current density associated with the Beltrami field and the imposed field generate a force varying along $x$, perpendicular to the components of the meso-scale Beltrami field. This generates a meso-scale velocity that in turn damps the Beltrami field, resulting in the slower rise in $\langle \mathbf{B}_0 \rangle$ as $B_0/B_{\text{eq}}$ is decreased. Further, the cross-product of the meso-scale velocity field with the Beltrami field generates a large-scale electromotive force in the $x$ direction. This is seen both in $\alpha_{\text{imp}}$ and in $\alpha_{xx}$. A rough estimate of this electromotive force can be obtained by considering the fields

\[ B_0 = \left( \begin{array}{c} B_0 \\ 0 \\ 0 \end{array} \right), \quad B_1 = B_1 \left( \begin{array}{c} \cos kx \\ \sin kx \end{array} \right), \]  

(23)

so that $\mu_0 \mathbf{J}_1 = -k \mathbf{B}_1$, where subscripts 1 denote meso-scale fields. The meso-scale current density and the imposed field will generate a meso-scale Lorentz force which will drive a meso-scale velocity field $U_1$. We estimate $U_1$ by balancing

\[ J_1 \times B_0/\rho + \nu_t \nabla^2 U_1 \approx 0, \]  

(24)

where $\nu_t$ is the turbulent viscosity. We therefore expect that $U_1$ will saturate for

\[ U_1 = \frac{B_0 B_1/\rho \mu_0}{\nu_t k} \left( \begin{array}{c} 0 \\ \sin kx \\ -\cos kx \end{array} \right). \]  

(25)

This velocity field will generate an $\mathbf{E}_0$ parallel to $B_0$ in conjunction with $B_1$

\[ \mathbf{E}_0 \equiv \langle U_1 \times B_1 \rangle = \alpha_{\text{meso}} B_0, \]  

(26)

with $\alpha_{\text{meso}} = B_1^2/(\rho \mu_0 \nu_t k)$. We then expect the total $\alpha_{\text{imp}}$ to be

\[ \alpha_{\text{imp}} = \alpha + \frac{B_1^2}{\rho \mu_0 \nu_t k}. \]  

(27)

Normalizing by $\alpha_0 = -u_{\text{rms}}/3$ and assuming $\nu_t \approx u_{\text{rms}}/3 k_t$ we find for small imposed field and a meso-scale dynamo that varies along $x$:

\[ \alpha_{\text{imp}}/\alpha_0 \approx 1 + \frac{k_t}{k_1} \left( \frac{B_1}{B_{\text{eq}}} \right)^2. \]  

(28)

Given that $k_t/k_1 = 3$ and noting that $B_1/B_{\text{eq}}$ reaches values up to 1.2, we find that $\alpha_{\text{imp}}/\alpha_0 \approx 40$, which is still somewhat below the actual value of 53, see the top panel of Fig. 3. The remaining discrepancy may be explicable by recalling that the actual value of $\nu_t$ may well be reduced due to the presence of an equipartition-strength magnetic field.

3.4 Comment on wavenumber dependence

In previous work on the test-field method we used test fields with wavenumbers different from zero. It turned out that in the kinematic regime, $\alpha$ is proportional to $1/(1 + a(k/k_t)^2)$, where $a = 0.5, \ldots, 1$ (Brandenburg, Rädler & Schrinner 2008; Mitra et al. 2009). It was shown that the variation of $\alpha$ with $k$ represents nonlocality in space. In order to get some idea about the dependence of $\alpha_{xx}$ and $\alpha_{yy}$ on $k$ in the present case we compare in Table 3 the results for $k = k_0$ with those for $k = 0$. It turns out that both values decrease by 30% on the X branch, and increase by less than 10% on the Z branch.

The $k$ dependence for the Z branch is minor, although one would have expected a small decrease rather than an increase. Nevertheless, within error bars, this result is possibly still compatible with the dependence in the kinematic case. For the X branch the
error bars for $k = 0$ are larger. This is because of the strong interaction between the imposed uniform field and a Beltrami field varying along the same direction, as discussed in Sect. 3.3. It is therefore not clear whether the $k$ dependence is here significant and how to interpret it.

### 4 RESETTING THE FLUCTUATIONS

#### 4.1 Effectiveness of resetting the fields

The evolution equations used both in the imposed-field method and in the test-field method allow for dynamo action. This led Ossendrijver et al. (2002) and Kapyla et al. (2006) to the technique of resetting the resulting magnetic field in regular intervals. This method is now also routinely used in the test-field approach (Sur et al. 2008), and we have also used it throughout this work. The lack of resetting the magnetic field may also be the main reason for the rather low values of $\alpha$ found in the recent work of Hughes & Proctor (2009); see the corresponding discussion in Kapyla et al. (2009).

In this section we employ the method of resetting $B$ to obtain better estimates for $\alpha$ for weak imposed fields, and to compare this with results from the test-field method. The result is shown in Fig. 6 where we show the dependence of $\alpha_{imp}$ on $B_0$ and on the reset interval $\Delta t$. We note that, in units of the turnover time, the reset interval $\Delta t u_{\text{rms}} k_f$ has a weak dependence both on $B_0$ and $\Delta t$, because small values of $B_0$ and $\Delta t$ quench $u_{\text{rms}}$ only weakly. The resetting technique has eliminated the branching for weak fields. For weak fields we find that the value of $\alpha_{imp}$ is slightly below $\alpha$, but this is partly because for finite scale separation there is an additional factor $(1 + k_f^2/k^2_{eq})^{-1} \approx 0.9$ (Brandenburg, Rädler & Schrinner 2008). The actual value of $\alpha_{imp}$ is somewhat smaller still, which may be ascribed to other systematic effects.

It turns out that over a wide range of reset intervals the resulting values of $\alpha_{imp}$ are not dependent in a systematic way on the reset interval (see also Mitra et al. 2009), although it is clear that the error bars increase for larger values of $\Delta t$. The same is true for the values of $\alpha_{xx}$ and $\alpha_{yy}$ obtained using the test-field method, except for the case of weak fields on the $X$ branch where the values of $\alpha_{xx}$ are ill-determined; see Table 3 where we compare the values of $\alpha_{xx}$ and $\alpha_{yy}$ for two different reset times in the case where $\alpha_{xx}$ is found to change sign ($R_m^{1/2} B_0/B_{eq} \approx 0.2$). The increasing fluctuations for longer reset intervals occur as the system exits the kinematic regime. It might therefore be possible to find indicators when the kinematic regime has been exited and resetting becomes necessary. However, we have not pursued this further in this work.

For even larger values of $\Delta t$ there is enough time for the meso-scale magnetic field to develop. An example is shown in Fig. 7 where 18 intervals of length $\Delta t u_{\text{rms}} k_f = 270$ are shown. For half of these intervals the wavevector of the Beltrami field begins to develop in the $x$ direction, so $\alpha_{imp}$ is heading toward the $X$ branch. In the other half of these cases the magnetic field is weak and $\alpha_{imp}$ lies on one of the other branches. None of these cases reproduce the correct kinematic value of $\alpha$, because we are not really considering a kinematic problem in this case. This underlines the importance of choosing reset intervals that are not too long.

Table 3. Examples of the dependence of $\tilde{\alpha}_{xx}$ and $\tilde{\alpha}_{yy}$ on the wavenumber $k$ of the test field. Note that the field strength is different in both cases.

| Branch | $k/k_0$ | $\tilde{\alpha}_{xx}$ | $\tilde{\alpha}_{yy}$ | $R_m^{1/2} B_0/B_{eq}$ |
|--------|---------|-----------------|-----------------|-----------------|
| X      | 0       | 0.72 ± 0.14     | 0.51 ± 0.16     | 0.06            |
|        | 1       | 0.61 ± 0.02     | 0.37 ± 0.01     | 0.06            |
| Z      | 0       | 0.34 ± 0.02     | 0.32 ± 0.02     | 0.2             |
|        | 1       | 0.35 ± 0.01     | 0.35 ± 0.02     | 0.2             |

Figure 6. Dependence of $\alpha_{imp}$ (solid lines) and $\alpha_{fit}$ (dotted lines) on the imposed field strength with fixed reset time $\Delta t u_{\text{rms}} k_f = 50,...,70$ (upper panel) and the dependence of $\alpha_{imp}$ on the reset time for $R_m^{1/2} B_0/B_{eq} = 0.1$ (lower panel). In all cases we have $R_m \approx 30$.

Figure 7. Time series of $\alpha_{imp}$ for $\Delta t u_{\text{rms}} k_f = 270$ with $R_m^{1/2} B_0/B_{eq} = 0.1$. The reset intervals are indicated by dotted vertical lines. In all cases we have $R_m \approx 30$. 

© 0000 RAS, MNRAS 000, 000–000
Table 4. Comparison of the results for \(\bar{\alpha}_{xx}\) and \(\bar{\alpha}_{yy}\) for two different reset times \(\Delta t\) for the examples of the X and Z branches with \(R_m^{1/2}B_0/B_{eq}=0.2\). The reset time is normalized by the inverse turnover time \((u_{turb}k_z)^{-1}\).

| Branch | \(\Delta t\) | \(\bar{\alpha}_{xx}\) | \(\bar{\alpha}_{yy}\) |
|--------|-------------|----------------|----------------|
| X      | 25          | -0.08 ± 0.13  | 0.54 ± 0.02   |
|        | 50          | -0.98 ± 0.09  | 0.70 ± 0.04   |
| Z      | 25          | 0.34 ± 0.02   | 0.32 ± 0.02   |
|        | 50          | 0.32 ± 0.01   | 0.33 ± 0.03   |

Our results support the hypothesis that the precise value of the reset time interval is not critical except for the field-aligned case where the diagonal components of the \(\alpha_{ij}\) tensor are large and quite uncertain, as indicated also by the large error bars. The sign-change found for \(\alpha_{xx}\) at low or intermediate field strengths might therefore not be real.

4.2 Time averaging in the test-field method

We have already demonstrated that the length of the reset interval is not critical for the value of \(\alpha\), but longer reset times tend to lead to larger errors. In the present section we demonstrate this for the test-field method using the idealized case where the turbulent flow velocity is replaced by simple stationary flow given by the equation

\[ U = k_z \phi \hat{z} + \nabla \times (\phi \hat{z}) , \]  

(29)

with

\[ \phi = \phi(x,y) = u_0 \cos k_0 x \cos k_0 y , \]  

(30)

which is known as the Roberts flow.

When the magnetic Reynolds number exceeds a certain critical value of around 60, some kind of dynamo action of \(b^\parallel\) commences. This type of dynamo is often referred to as small-scale dynamo action (Sur et al. 2008; Brandenburg et al. 2008; Cattaneo & Hughes 2009), but this name may not always be accurate. In the case of the Roberts flow there would be no such dynamo action if the wavenumber of the test field is zero, \(k = 0\), as assumed here. However, for \(k = k_0\), for example, dynamo action for the test-field equation is possible. The test fields are therefore chosen to be

\[ \overline{\mathbf{B}}^\parallel = \begin{pmatrix} \cos k z \\ 0 \\ 0 \end{pmatrix} , \quad \overline{\mathbf{B}}^\perp = \begin{pmatrix} \sin k z \\ 0 \\ 0 \end{pmatrix} \quad \text{(31)} \]

\[ \overline{\mathbf{B}}^\parallel = \begin{pmatrix} 0 \\ \cos k z \\ 0 \end{pmatrix} , \quad \overline{\mathbf{B}}^\perp = \begin{pmatrix} 0 \\ \sin k z \\ 0 \end{pmatrix} , \quad \text{(32)} \]

see (Sur et al. 2008). Since now the mean fields are also functions of \(z\), the term \(u_0 \times b^\perp\) cannot be omitted in equation (3). As stressed by (Brandenburg, Rädler & Schrömer 2008), in the expression for the electromagnetic force there is general also a contribution \(\overline{\mathbf{E}}_0\) that is independent of the mean field. Given that test fields \(\overline{\mathbf{B}}^\parallel\) are independent of time, we have

\[ \overline{\mathbf{E}}^\parallel(z,t) = \overline{\mathbf{E}}_0^\parallel(z,t) + \alpha(z) \overline{\mathbf{B}}^\parallel(z) - \eta_r(z) \mu_0 \overline{\mathbf{J}}^\parallel(z) , \quad \text{(33)} \]

where overbars denote \(xy\) averages (not volume averages), so there is also a term \(\eta_r \mu_0 \overline{\mathbf{J}}^\parallel\), where \(\eta_r\) is the turbulent magnetic diffusivity. We have assumed that \(\alpha\) and \(\eta_r\) are independent of time, and in this case they are also independent of \(z\). The \(\overline{\mathbf{E}}^\parallel_0(z,t)\) term can be eliminated by averaging over time, i.e. \(\langle \overline{\mathbf{E}}_0^\parallel \rangle = 0\), so

\[ \overline{\mathbf{B}}^\parallel = \alpha \overline{\mathbf{B}}^\parallel - \eta_r \mu_0 \overline{\mathbf{J}}^\parallel . \quad \text{(34)} \]

In Fig. 8 we show the evolution of \(\alpha\) for the Roberts flow with \(R_m = 65\) and 55. In the case with \(R_m = 65\) there are exponentially growing oscillations corresponding to a wave traveling in the \(z\) direction. In general such fields can be a superposition of waves traveling in the positive and negative \(z\) directions. It is seen quite clearly that the running time average is stable and well defined. The results for \(R_m = 65\) and 55 are close together (\(\alpha/\alpha_0 = 0.096\) and 0.090, respectively), suggesting continuity across the point where dynamo action sets in. This supports the notion that averaging over time is a meaningful procedure.

5 CONCLUSIONS

The present simulations have shown that the imposed-field method leads to a number of interesting and unexpected results. For imposed fields exceeding the value \(R_m^{1/2}B_0/B_{eq}\) one recovers the catastrophic quenching formula of Vainshtein & Cattaneo (1992); see equation (15). We emphasize once more, however, that this formula is only valid for completely uniform large-scale fields in a triply-periodic domain. This is clearly artificial, but it provides an important benchmark.

A number of surprising results have been found for weaker fields of less than \(R_m^{1/2}B_{eq}\). In virtually none of those cases does the imposed-field method recover the kinematic value of \(\alpha\). Instead, \(\alpha_{\text{imp}}\) can attain strongly suppressed values, but it can actually also attain strongly enhanced values. This is caused by the unavoidable emergence of meso-scale dynamo action. In principle, such meso-scale dynamo action could have been suppressed by restricting oneself to scale-separation ratios, \(k_1/k_2\), of less
than 2 or so. This was done, for example, in some of the runs of Brandenburg & Subramanian (2005a). In the present case of a triply-periodic box, four different magnetic field configurations can emerge. The first three correspond to Beltrami fields, where the wavevector points in one of the three coordinate directions. The fourth possibility is also a Beltrami field, but one that varies diagonally in a direction perpendicular to the direction of the imposed field. The latter was found to be unstable in the absence of an imposed field, but they can be long-lived in the present case of an imposed field.

In this paper, we have used the term meso-scale fields to refer to the Beltrami fields naturally generated by the helicity-driven dynamo in our system. A more general definition of meso-scale fields would encompass all fields that break isotropy, average to zero, and yet do not time-average to zero. In the absence of such fields, mean-field theory can be applied in a straightforward manner. This is indeed the case that one is normally interested in. However, when such meso-scale fields exist, they must be understood for determining turbulent transport coefficients, because those coefficients apply then to the particular case of saturated meso-scale fields.

The results obtained with the imposed-field method reflect correctly the circumstances in the nonlinear case where the α effect is suppressed by dynamo-generated meso-scale magnetic fields whose scale is smaller than that of the imposed field, but comparable to the scale of the domain. Especially in the case of closed or periodic domains the resulting α is catastrophically quenched, which is now well understood (Field & Blackman 2002; Blackman & Brandenburg 2003). This effect is particularly strong in the case where one considers volume averages, and thus ignores the effects of turbulent magnetic diffusion. With magnetic diffusion included, both α and η have only a mild dependence on $R_m$ (Brandenburg et al. 2008b). However, astrophysical dynamos are expected to operate in a regime where magnetic helicity fluxes alleviate catastrophic quenching; see Brandenburg & Subramanian (2005b) for a review.

Determining the nature of the dynamo mechanism is an important part in the analysis of a successful simulation showing large-scale field generation. Our present analysis shows that meaningful results for α can be obtained using either the imposed-field or the test-field methods provided the departure of the magnetic field from $B_0$ is reset to zero to eliminate the effects of dynamo-generated meso-scale magnetic fields. Conversely, if such fields are not eliminated, the results can still be meaningful, as demonstrated here, but they need to be interpreted correspondingly and bear little relation to the imposed field. On the other hand, for strong imposed magnetic fields ($R_m B_0^2 / B_{eq}^2 > 1$), meso-scale magnetic fields tend not to grow, so the resetting procedure is then neither necessary nor would it make much of a difference when the test-field method is used. However, when the imposed-field method is used, the resetting of the actual field reduces the quenching of $\alpha_{\text{imp}}$. This affects the normalizations of $B_0$ and $\alpha_{\text{imp}}$ with $B_{eq}$ and $\alpha_0$, respectively, because both are proportional to $\alpha_{\text{imp}}$.

Throughout this paper we have considered relatively moderate values of $R_m$, but we computed a large number of different simulations. In the beginning of this study we started with larger values of $R_m$ and found that the resulting $\alpha_{\text{imp}}$ seemed inconsistent. In hindsight it is clear what happened: the few cases that we had in the beginning were all scattered around different branches. Only later, by performing a large number of simulations at smaller values of $R_m$ it became clear that there are indeed different branches. This highlights the importance of studying not just one or a few models of large $R_m$, but rather a larger systematic set of intermediate cases of moderate $R_m$ where it is possible to understand in detail what is going on. It will be important to continue exploring the regime of larger $R_m$, and we hope that the new understanding that emerged from studying cases of moderate $R_m$ proves useful in this connection. According to the results available so far, we can say that for larger values of $R_m$ the turbulent transport coefficients are only weakly affected (see Brandenburg et al. 2008b, for $R_m < 600$) for fields of equipartition strength, or not affected at all (Sur et al. 2008, for $R_m \leq 220$) if the field is in the kinematic limit.

ACKNOWLEDGMENTS

We thank the referee for making a number of constructive remarks on the paper.
