Introduction

Patent ductus arteriosus (PDA) in the very low birth weight premature newborn (VLBWPN) is currently treated with medical therapy or by surgical ligation. The objective of this mini-review and brief case report is to highlight the potential side effects of medical therapy (indomethacin or ibuprofen) including bronchopulmonary dysplasia (BPD), necrotizing enterocolitis (NEC), intraventricular hemorrhage (IVH), bowel perforation, pulmonary edema and bleeding, retinopathy, thrombocytopenia, and decrease in renal function and present an example of a patient frequently encountered in the neonatal intensive care unit that dramatically improved with prompt surgical intervention. Secondary objective is to support a more proactive approach toward early surgical ligation and highlight factors in VLBWPN who might be at the greatest risk and might benefit from earlier intervention. Currently PDA ligation is generally performed in the cases in which indomethacin or ibuprofen medication is unsuccessful or contraindicated. Given the side effects of indomethacin or ibuprofen medical therapy, it is important to recall the risks of nonoperative management of VLBWPN and to consider earlier utilization of surgical ligation.

Case Report

Patient was a fourteen day old female born premature at 24 weeks gestation. She was born via caesarian section due to preterm premature rupture of membranes and fetal intolerance to labor with a birthweight of 490 grams. She was noted to have Apgar scores of 5 and 8 and required immediate neonatal resuscitation with intubation for respiratory distress syndrome (RDS). Patient was admitted to the neonatal intensive care unit (NICU) for closer monitoring. At the time of consultation, she was tolerating feeds and weighted 560 grams but continued to require mechanical ventilation with inability to wean FiO2 (upper 40%). A transthoracic ECHO cardiogram was performed in the immediate postpartum period and found to be consistent with a large PDA with left to right shunting.

Abstract

Patent ductus arteriosus (PDA) in the very low birth weight premature newborn (VLBWPN) is currently treated with medical therapy or by surgical ligation. The objective of this mini-review and brief case report is to highlight the potential side effects of medical therapy (indomethacin or ibuprofen) including bronchopulmonary dysplasia (BPD), necrotizing enterocolitis (NEC), intraventricular hemorrhage (IVH), bowel perforation, pulmonary edema and bleeding, retinopathy, thrombocytopenia, and decrease in renal function and present an example of a patient frequently encountered in the neonatal intensive care unit that dramatically improved with prompt surgical intervention. Given the side effects of indomethacin or ibuprofen medical therapy, it is important to consider earlier utilization of surgical ligation.
The patient subsequently underwent attempted medical therapy for closure of PDA with two courses of indomethacin. Repeat transthoracic echocardiogram on day of life eleven was found to be consistent with persistent moderate PDA with continued left to right shunting with a gradient of 25-30mmHg across the PDA. Other pertinent past medical history was significant for questionable germinal matrix bleed, extreme prematurity and respiratory failure. Other imaging included serial daily chest x-rays consistent with RDS with bilateral fluid overload that was unresponsive to Lasix.

Surgery was performed in the NICU; the patient was positioned in the right lateral decubitus position and all pressure points were padded. The left chest was preppped and draped. A posterior lateral thoracotomy was performed with Bowie electrocautery just inferior to the tip of the scapula and blunt dissection was performed down to the subcutaneous tissues; the latissimus dorsi muscle was divided. The serratus muscle was then retracted anteriorly and the third interspace was identified. The electrocautery was further used to divide the intercostal muscles and the left chest was entered. The aorta, recurrent laryngeal nerves, subclavian artery, and the ductus arteriosus were identified; grossly normal anatomy was noted. Dissection was then carried out inferiorly and superiorly to the patent ductus arteriosus after the overlying pleura was opened. A test clamp was then performed which she tolerated well. A medium clip was applied to the ductus, and it was noted to occlude completely. The lung was reinflated and the ribs reapproximated "with two 3-0 interrupted Vicryl sutures. Likewise the muscles were reapproximated and finally the skin was closed in a subcuticular fashion. The postoperative chest x-ray showed the clip in good position and the lungs adequately reexpanded. The immediate postoperative course was uneventful and the postoperative day one chest x-ray revealed dramatic resolution of bilateral pulmonary infiltrates (Figure 1). The FiO2 was quickly weaned to the low 30’s without difficulty. The neonate resumed feedings on postoperative day one.

Figure: 1: Demonstration of dramatic interval improvement near totally opacification of lungs Pre (left) and postoperative day 1 (right) PDA ligation.

Discussion

Surgical PDA ligation is generally utilized after medical therapy with indomethacin or ibuprofen has been unsuccessful at closure. Thoracotomy (eventually done bedside in the neonatal unit to avoid transport) has been the standard of care for treating large, symptomatic, or persistent PDAs since its inception in 1938 [3]. In a study by Trust et al, they found for infants under 800 g, the failure rate for PDA closure with indomethacin was found to be as high as 40%-50% [5]. In addition, indomethacin treatment in VLBWPN has numerous severe side effects such as necrotizing enterocolitis, bowel perforation, pulmonary edema and bleeding, retinopathy, thrombocytopenia, and increase in renal failure [1]. Furthermore, other studies have clearly shown that the incidence of NEC and the duration of TPN were significantly decreased in premature infants with early surgical ligation of symptomatic PDA that was refractory to medical treatment [6].

As highlighted by Weisz et al, it is important to note that many of the observational studies on the treatment of PDA do not adequately account for confounding by indication [7]. In other words, it may be that PDA ligation is a surrogate marker for increased illness severity, as "sicker" infants may be more likely to be referred for ligation and therefore surgical ligation is generally not considered until medical treatment has failed or was contraindicated [7]. Studies to date have inadequately addressed this confounding by indication.

The results from previous studies by Grosfeld et al and Cassady et al support an opinion, that VLBWPN should undergo early surgery as the treatment of choice [8,9]. The defined interval from failed medical management in the VLBWN to surgical ligation has not been defined and is likely multifactorial in nature. Therefore, a brief period of conservative medical management for VLBWN with PDA may be a reasonable approach, but without rapid resolution and success with drugs, surgical closure of PDA, generally assured and complete with one attempt, remains the gold standard of treatment and should not be delayed.
