Herpes Simplex Encephalitis Complicated by Cerebral Hemorrhage during Acyclovir Therapy

Yukinori Harada and Yuuta Hara

Abstract

Herpes simplex encephalitis (HSE) can be complicated by adverse events in the acute phase. We herein present the case of a 71-year-old woman with HSE complicated by cerebral hemorrhage. She presented with acute deterioration of consciousness and fever and was diagnosed with HSE based on the detection of herpes simplex virus-1 in the cerebrospinal fluid by a polymerase chain reaction. The cerebral hemorrhage developed during acyclovir therapy; however, its diagnosis was delayed for 2 days. After the conservative treatment of the cerebral hemorrhage, the patient made a near-complete recovery. Cerebral hemorrhage should be considered as an acute-phase complication of HSE.

Key words: cerebral hemorrhage, herpes simplex encephalitis

Introduction

Without appropriate management, Herpes simplex encephalitis (HSE) is a potentially fatal disease (1). The mortality and morbidity rates remain high, even when an early diagnosis is made based on the detection of the herpes simplex virus (HSV) in the cerebrospinal fluid (CSF) by a polymerase chain reaction (PCR), and despite the advent of acyclovir therapy (2). In particular, the acute-phase mortality and long-term outcome in patients with severe HSE remain major concerns (3). Although the severity and poor outcomes of HSE are mostly associated with acute-phase complications (2, 3), these important adverse events are not well understood because of the low frequency of the condition and the paucity of reported cases. This lack of understanding may contribute to a lack of awareness by clinicians and, consequently, to the poor outcomes of patients with HSE. We herein report the case of a patient with HSE that was complicated by cerebral hemorrhage (the diagnosis of which was delayed), which developed at the end of 2 weeks of acyclovir therapy.

Case Report

A 71-year-old woman was admitted to our hospital in a state of unconsciousness following fever and headache. She experienced epigastric discomfort and dizziness 8 days before admission and gradually lost her appetite. Two days later, she developed a fever of 38.2°C, headache, and nausea. She was evaluated twice by the outpatient service of our hospital for fever and was prescribed acetaminophen both times. However, in addition to the persistence of fever and headache, there was an acute worsening of her state of consciousness on the day of admission, and she was transported to our emergency department by ambulance. The patient was placed under observation for 4 years at another hospital due to the presence of an unruptured aneurysm of the right middle cerebral artery. In addition, she had undergone bilateral cataract surgery 3 years previously. She had no medical history of immunodeficiency. There was no family history of sudden death or intracranial hemorrhage. She was not taking any regular medications. The patient was a non-smoker and did not regularly consume alcohol.

On physical examination, her Glasgow coma scale (GCS) score was E1V1M4, her body temperature was 38.8°C, her blood pressure was 116/66 mmHg, her pulse rate was 80/
min, and her respiratory rate was 16/min with an O₂ saturation of 99% (with a flow rate of 3 L/min). Her pupils were round and equally dilated (size, 3 mm). A head and neck examination revealed no anemia, icterus, or other abnormalities. The results of a cardiovascular examination were normal, and auscultation revealed normal lung sounds. An abdominal examination was unremarkable with no obvious hepatosplenomegaly. A neurological examination revealed no neck stiffness and normal deep tendon reflexes; however, slightly rigid muscle tone and bilateral pathological Babinski reflexes were observed.

Laboratory investigations revealed a normal white blood cell count (7,350/μL), a slightly elevated C-reactive protein (0.36 mg/dL) level, elevated lactate dehydrogenase (313 IU/L) and creatine kinase (939 IU/L) levels, hyponatremia (128 mEq/L), hypokalemia (2.9 mEq/L), hypochloremia (88 mEq/L), and a normal blood glucose level (126 mg/dL). A urinalysis revealed no abnormal findings. A chest X-ray and electrocardiogram revealed no abnormalities. The right anterior medial temporal lobe and insular cortex displayed high signal intensity on T2-weighted and diffusion-weighted brain magnetic resonance imaging (Fig. 1A-C), and the patient’s aneurysm, which was already known to exist, was observed at the bifurcation of the distal M1 segment of the middle cerebral artery using magnetic resonance angiography (Fig. 1D). A CSF analysis detected moderate lymphocytic leukocytosis (170/μL), a moderately increased protein level (77 mg/dL), and a slightly decreased glucose level (53 mg/dL). Gram staining of the patient’s CSF was negative, and blood and CSF cultures showed no bacterial growth. A PCR of the CSF to detect HSV-1 and HSV-2 revealed the presence of HSV-1 DNA. She was therefore diagnosed with HSE.

The patient was treated with acyclovir (10 mg/kg, intravenously, three times per day [ideal body weight]), glycerol (200 mL, intravenously, twice a day), and additional supportive therapies. Although the patient vomited on the day of admission, her symptoms disappeared within the first 2 days. Her consciousness gradually recovered to GCS E4V4M6, and her temperature returned to 37.3°C on day 11 after admission. However, she vomited during the night on day 12, and her GCS slightly worsened to E3V4M6, and she displayed a slightly elevated body temperature of 37.6°C on day 13. An exacerbation of HSE was considered, and a CSF analysis including a PCR for HSV-1 was performed, which revealed mild bloody fluid with moderate lympho-

Magnetic resonance angiography (D) shows an aneurysm at the bifurcation of the distal M1 segment of the right cerebral artery.
Acyclovir therapy was terminated based on the results of the second PCR for HSV, which was negative. After 2 months of rehabilitation, the patient made a near-complete recovery. There was no recurrence of encephalitis or intracranial hemorrhage.

**Discussion**

We herein report a case of cerebral hemorrhage that developed in a patient who was undergoing acyclovir treatment for HSE. Although the patient made a near-complete recovery, the diagnosis of the cerebral hemorrhage was delayed. Initially, an acute exacerbation of HSE was considered, as intracranial vascular disease was not included in the differential diagnosis. This case suggests that acute-phase complications of HSE need to be better understood to avoid missing the onset of adverse events that can be managed successfully if they are diagnosed early.

The patient’s cerebral hemorrhage appears to have been associated with HSE due to the following reasons. First, the site of hemorrhage was consistent with the region in which HSE-associated inflammation was observed. Second, the timing of the onset of hemorrhage was typical for HSE-related cerebral hemorrhage (4). Although the precise cause of cerebral hemorrhage in HSE patients remains unclear, based on the pathological findings in similar cases, we hypothesize that the rupture of the small vasculitic vessels of the brain due to HSV-induced inflammation was a possible mechanism of our patient’s bleeding (5, 6).

In addition to cerebral hemorrhage (4), seizures (2, 3), increased intracranial pressure (3, 7-10), stroke (11, 12), subarachnoid hemorrhage (13), and central diabetes in-
show any improvement during acyclovir treatment. and re-perform imaging studies in HSE patients who do not cerebral hemorrhage and other acute-phase complications worsening of encephalitis. Clinicians should consider similarity of its symptoms to the primary disease and due to treatment.

In conclusion, the diagnosis of cerebral hemorrhage during the early phase of HSE may be delayed because of the similarity of its symptoms to the primary disease and due to the worsening of encephalitis. Clinicians should consider cerebral hemorrhage and other acute-phase complications and re-perform imaging studies in HSE patients who do not show any improvement during acyclovir treatment.

The authors state that they have no Conflict of Interest (COI).
