Assessment of the subclinical myocardial
dysfunction with preserved left ventricle ejection
fraction in type 2 diabetes mellitus patients with
global myocardial work

Abstract

To assess the subclinical left ventricle(LV) myocardial dysfunction in preserved left ventricle ejection fraction(LVEF) in type 2 diabetes mellitus(T2DM) patients by global myocardial work(MW). 60 untreated T2DM patients and 60 normal controls were enrolled for this study. Apical 4-, 3- and 2- chamber views were acquired by two-dimensional echocardiography. Peak systolic myocardial layer-specific global longitudinal strain(GLS), peak strain dispersion(PSD), global myocardial work index(GWI), global constructive work(GCW), global wasted work(GWW), and myocardial work efficiency(GWE) were generated by speckle-tracking echocardiography(STE). The values of GLS in T2DM patients were significantly lower than normal controls(p < 0.05). GWW in T2DM patients was significantly larger than normal controls, while GWE was significantly lower(p < 0.05). In T2DM patients, fasting plasma glucose positively correlated with GWW, while negatively correlated with GWE, respectively. ROC analysis showed GWE was superior to other values with a highest AUC of 0.688. Logistic regression analysis indicated that GLSEndo (OR = 1.196, 95% CI: 1.012–1.414, p = 0.036), and GWE (OR = 0.585, 95% CI: 0.414–0.825, p = 0.002) were independent risk factors associated with LV function in T2DM patients. From the research, the subclinical LV myocardial dysfunction was detected by GLS and global MW in T2DM patients. Global MW is a sensitive predictor to demonstrate the subclinical LV myocardial dysfunction in T2DM patients.

Introduction

Type 2 diabetes mellitus (T2DM) is increasing worldwide in recent years. The development of coronary artery disease (CAD) induced by T2DM has been also increased. In the past few years, cardiovascular disease becomes the major cause of morbidity and mortality for T2DM patients[1]. The pathological changes of diabetic induced cardiomyopathy mainly contain cardiomyocyte apoptosis, myocardial fibrosis and necrosis, at last, lead to cardiac systolic and diastolic dysfunction and heart failure[2; 3]. Therefore, in order to protect the cardiac function, early detection and intervention the function of left ventricle (LV) is essential to the prevention and management of diabetic cardiomyopathy.

There were a lot of techniques can assess the cardiac function, such as cardiovascular magnetic resonance T1 mapping[4], Tc-99m MIBI gated single-photon emissione-computed tomography (SPECT) myocardial perfusion imaging[5], tissue Doppler strain echocardiography[6], and two-dimensional speckle tracking echocardiography (2D-STE)[7; 8]. However, these techniques are all have their limitations. Like angle-dependence in tissue Doppler strain echocardiography, long-time examination in cardiac MRI and the radioactivity of the cardiac radionuclide imaging. 2D-STE has a lower signal-to-noise ratio, weak acoustic windows, and through-plane motion artifacts[9; 10]. However, 2D-STE has become the leading reliable diagnostic techniques for assessment of the cardiac functions because of its noninvasiveness, convenience, and repeatability. In addition, our group previously reported that LV longitudinal myocardial function detected by longitudinal strain and rotation in T2DM patients with preserved LV ejection fraction (LVEF) was impaired when compared with healthy subjects[11]. However, global myocardial work (MW) is a new parameter for 2D-STE that takes into account deformation as well as afterload through
interpretation of strain in relation to dynamic non-invasive LV pressure, potentially offering incremental value to myocardial function assessment.

The aim of the research was to explore the incremental value of MW in the detection the subclinical LV myocardial dysfunction of T2DM patients with preserved LV systolic function.

Subject And Methods

Study population

60 untreated T2DM patients and 60 normal controls of similar age and gender were enrolled for this study were recruited from the hospital. The inclusion criteria for T2DM patients were clinically confirmed subjects in accordance with the World Health Organization criteria[12] without any history of heart disease (congenital heart disease, coronary artery disease, arterial hypertension, myocardial infarction, cardiomyopathy, valvular disease, atrial fibrillation, thyroid disease, neoplastic disease, or kidney failure). All the T2DM patients had a LVEF > 55%. The normal controls were recruited from the physical examination or surgery in the hospital. In the normal controls, all of the physical and laboratory examination tests about cardiac function, the electrocardiogram (ECG), and the echocardiography were showed normal.

Anthropometric and biochemistry

The sex, age, height, body weight, and blood pressure of all subjects were recorded at the time of the echocardiography examination. Fasting plasma glucose, two-hour postprandial blood sugar and glycated hemoglobin (HBA1c) were measured when the patients in hospital.

Conventional 2D Doppler echocardiography

Conventional 2D transthoracic Doppler echocardiography by Vivid E9 equipped with an M5S 3.5-5 MHz transducer (GE Vingmed Ultrasound, Horten, Norway) were performed to these patients by an experienced cardiologist. All of the patients were connected ECG leads. Apical 4-chamber, 2-chamber, and long-axis views of three consecutive cycles with standard high frame rate (>60 s⁻¹) were stored for offline analysis.

Echocardiographic parameters of left atrial diameter (LAd), interventricular septum thickness (IVSd), LV posterior wall thickness (LVPWd) and LV diameter (LVDd) in end-diastole period, the peak early (E) and late (A) diastolic mitral annular velocities, LV end-diastole volume (LVEDV), LV end-systole volume (LVESV) and LVEF (modified biplane Simpson's method), The peak early (e') and late (a') diastolic annular velocities (obtained by averaging the values at the septum and lateral wall by tissue Doppler imaging (TDI).) were measured during the examination (Figure 1).

Two-Dimensional STE
Layer specific longitudinal strain (epimyocardial, middle myocardial and endomyocardial), peak strain dispersion (PSD), MW were measured by the software of EchoPAC (EchoPAC Version: 203, GE Vingmed Ultrasound, Norway).

First, identify the aortic valve closure time from the event timing of aortic valve spectrum. Then using the APLAX, A4C and A2C for analysis the apical long-axis, four-chamber and two-chamber views. The LV myocardial was divided into 18 segments, and layer specific global longitudinal strain (GLS) of epimyocardial, middle myocardial and endomyocardial were automatically measured by the software (Figure 2A).

MW and related indices were calculated using a combination of echocardiographic strain data and a noninvasively estimated LV pressure curve. Input the blood pressure into the software, and click the keyboard "Advanced", then MW and related indices were calculated using a combination of echocardiographic strain data and a noninvasively estimated LV pressure curve[13]. (1) GWI: global myocardial work index, (2) GCW: global constructive work. (3) GWW: global wasted work. (4) GWE: myocardial work efficiency, GWE= GCW/(GCW+GWW).

**Statistical analysis**

All data analyses were performed using SPSS 25.0 software (SPSS, Chicago, IL, USA). Data were presented as the mean ± standard deviation (SD). p-value < 0.05 was considered statistically significant in all tests. Shapiro-Wilk's test or Kolmogorov-Smirnov's test was used to detect the normality of all values. Differences between T2DM patients and normal controls were compared with an independent Student's t-test for the data distribution was normal. For variables with a non-normal distribution, the nonparametric Mann-Whitney test was used. We defined layer specific strains, PSD, MW values in normal controls as the normal state, and considered the values of T2DM patients as abnormal. These values in T2DM patients were determined from receiver operating characteristic (ROC) curve analysis. Yoden’s index was selected for the cut-off point which can give the best composite of specificity and sensitivity. Correlations among LVEF, fasting plasma glucose, HbA1c and layer specific strains, PSD, MW values were tested using Pearson or Spearman correlation tests as appropriate. Logistic regression analysis was performed to assess independent correlates of LV function of T2DM patients. Odds ratio (OR) with 95% CI was estimated.

**Reproducibility and repeatability**

Intraobserver and interobserver variability for layer specific GLS, PSD, MW values were determined by repeating measurements in random selected 25 patients among all enrolled patients.

**Results**

Patients Characteristics
120 patients satisfied the baseline inclusion criteria. 19 patients were excluded from strain and MW analysis because of inadequate image quality (n=12), tachycardia (n=5) and irregular heartbeat (n=2). A total of 111 patients were therefore evaluated in the study and were initially divided into two groups, normal controls (n=53, mean age, 49.96±13.17 years, 28 men) and T2DM patients (n=48, mean age, 53.79±11.24 years, men).

 Patients characteristics data and conventional echocardiographic parameters in normal controls compared with T2DM patients (Table 1).

The values of BSA, SBP, fasting plasma glucose and HbA1c were significantly larger in T2DM patients compared with normal controls (p<0.05). There were no significant differences in age, heart rate, sex and DBP between normal controls and T2DM patients.

The values of LAd, IVSd, a' and E/e' in T2DM patients were significantly larger than normal controls (p<0.05), however, LVEF and e’ in T2DM patients were significantly lower than normal controls (p<0.05). There were no significant differences in LVPWd, LVDd, LVEDV, LVESV, E and A between normal controls and T2DM patients (p>0.05).

LV GLS of different myocardial layers and global MW between normal controls and T2DM patients (Table 2, Figure 3).

The values of LV GLS (epimyocardial, middle-layer myocardial and endomyocardial) in T2DM patients were significantly lower than normal controls (p<0.05). The value of PSD in T2DM patients was significantly larger than normal controls (p<0.05). The value of GWW was significantly larger in T2DM patients compared with normal controls, however, the value of GWE was significantly lower in T2DM patients compared with normal controls (p<0.05). There were no significant differences in GWI and GWE between normal controls and T2DM patients (p>0.05), however, the values were a litter lower in T2DM patients when compared with normal controls.

Receiver operating characteristic curve analysis (Table3, Figure 4)

GWE was superior to other values with an AUC of 0.688. According to the receiver operating characteristic curve analysis, the optimal cutoff value for GWE for the detection of patients diagnosed was 94 %, with sensitivity of 25 %, specificity of 100%, and the Youden index was 0.25.

Correlation tests among LVEF, fasting plasma glucose, HbA1c and LV systolic functions (Figure 5, 6 and 7).

In total population, LVEF negatively correlated with GLSEpi, GLSMid, and GLSEndo. Fasting plasma glucose positively correlated with GLSEpi, GLSMid, GLSEndo and GWW, while negatively correlated with GWE. HbA1c positively correlated with GLSMid, GLSEndo and GWW, while negatively correlated with GWE. In normal controls, HbA1c positively correlated with GWI, GCW and GWE, while negatively correlated
with GWW. In T2DM patients, fasting plasma glucose positively correlated with GWW, while negatively correlated with GWE, respectively.

**Risk factors for LV function of T2DM patients (Table 4).**

Logistic regression analysis was applied, where the variables were selected because they were associated with LV function of T2DM patients with a p value < 0.05 (LVEF, GLSEpi, GLSMid, GLSEndo, PSD, GWW, GWE). It indicated that GLSEndo (OR=1.196, 95% CI: 1.012-1.414, p=0.036), and GWE (OR=0.585, 95% CI: 0.414-0.825, p=0.002), were independent risk factors associated with LV function of T2DM patients.

**Intra- and Interobserver Variability (Table 5)**

Intraclass correlation coefficient (ICC) of measurement by intra- and interobserver variabilities were calculated. All GLS of different layers and global MW parameters showed excellent intra- and interobserver correlation with ICC values > 0.85.

**Discussion**

The main finding of the study was: the subclinical LV myocardial dysfunction was detected in T2DM patients with preserved LV systolic function. Global MW was a sensitive predictor for detecting the subclinical LV myocardial dysfunction in T2DM patients. Fasting plasma glucose maybe a predict factor to cardiac MW.

The cardiac impaired by T2DM contained microvascular impairment, metabolic disturbance, subcellular component abnormalities, cardiac autonomic dysfunction, and a maladaptive immune response. Eventually, functional and structural changes in the myocardium without coronary artery disease were caused by T2DM, the disorder is called diabetic cardiomyopathy[14]. Diabetic cardiomyopathy may first induce diastolic dysfunction, and then systolic dysfunction. Lastly, the clinical heart failure maybe occurred. With the development of image examination, detection the cardiac function becomes ever more and more easy. Echocardiography for measuring the MW was considered the newest tool for the assessment of LV systolic dysfunction. Billig S[15], et al evaluated left and right ventricular structure, function and myocardial work by transesophageal echocardiography (TEE) in swine, and found that myocardial contractility and mechanics could be reliably evaluated with the non-invasive GWI derived from echocardiography without additional invasive measures. Galli E[16], et al provided the reference values for GWI, GCW, GWW and GWE in a group of healthy volunteers accounting for age and gender, and found that the assessment of MW is feasible in normal subjects. The presented referral ranges of GWI, GCW, GWW and GWE were not affected by age. According to the previous studies, MW have been reported in the coronary heart disease[17], hypertension, cardiac resynchronization therapy(CRT), percutaneous coronary intervention (PCI)[18], aortic stenosis[19], transcatheter aortic valve replacement (TAVR)[20], dilated cardiomyopathy[21], hypertrophic cardiomyopathy[22], chronic kidney disease[23], cardiac amyloidosis[24] and so on. However, there was little research about the LV systolic function in T2DM patients with MW.
Liu JH[25], et al provided prognostic value in T2DM patients by GLS and found that in T2DM patients without any history of cardiovascular disease, impaired GLS was associated with cardiovascular events. Our research was according with this research, and we found that layer-specific LV GLS was decreased in T2DM patients when compared with normal controls. MW analysis had shown that the value of GWW was significantly larger in T2DM patients compared with normal controls and the value of GWE was significantly lower in T2DM patients compared with normal controls. Although there were no significant differences in GWI and GWE between normal controls and T2DM patients, the values were a litter lower in T2DM patients when compared with normal controls. The results may conclude that the subclinical LV myocardial dysfunction was detected in T2DM patients although the LV systolic function was normal. We considered the results were related to the pathological changes of LV myocardium in T2DM. In T2DM, persistent hyperglycemia causes the molecular and metabolic changes in cardiomyocytes and damages the coronary microvasculature. Hypoxia of cardiomyocytes and ischemia results myocardial hypertrophy, perivascular and fibrosis, LV stiffness, and systolic and diastole dysfunction in T2DM[14]. A normal myocardial fiber consists of longitudinal and circumferential myocardial fibers. Almost 70% of the myocardial fiber is longitudinal and 30% is circumferential. If there was cardiomyocyte apoptosis, myocardial fibrosis and necrosis in T2DM, the sequence of myocardium may change, and eventually lead to the damage of myocardial systolic function, also the reduced PSD could prove the dysfunction.

In total population, LVEF negatively correlated with GLSEpi, GLSMid, and GLSEndo. Fasting plasma glucose positively correlated with GLSEpi, GLSMid, GLSEndo and GWW, while negatively correlated with GWE. HbA1c positively correlated with GLSMid, GLSEndo and GWW, while negatively correlated with GWE. In normal controls, HbA1c positively correlated with GWI, GCW and GWE, while negatively correlated with GWW. In T2DM patients, fasting plasma glucose positively correlated with GWW, while negatively correlated with GWE, respectively.

In this study, we evaluated the risk factors of LV function in T2DM patients. It indicated that GLSEndo (OR = 1.196, 95% CI: 1.012–1.414, P = 0.036), and GWE (OR = 0.585, 95% CI: 0.414–0.825, P = .002), were independent risk factors associated with LV function of T2DM patients. Thus, taking into account for GLSEndo and GWE status might further improve LV function of T2DM patients.

**Conclusion**

From the research, we found that the subclinical LV myocardial dysfunction is detected in T2DM patients with preserved LV systolic function. Global MW is a sensitive predictor to demonstrate the subclinical LV systolic dysfunction in T2DM patients with preserved LV systolic function. Different levels of fasting plasma glucose maybe a predict factor for MW in T2DM patients.
