Abstract

Background: Influenza surveillance is important for monitoring influenza virus circulation and disease burden to inform influenza prevention and control measures. The objective of this study was to describe the epidemiology and estimate the incidence of influenza in two small communities in West Java, Indonesia, before and after the 2009 H1N1 pandemic.

Methods: A population-based surveillance study in the community health care setting was conducted to estimate the annual incidence of influenza. Real-time reverse transcription polymerase chain reaction assay was used for influenza case ascertainment. Results: The mean annual incidence of influenza A and B, adjusted for health care utilization, was 1.6 (95% CI 1.3-2.0) and 0.7 (95% CI: 0.5-1.0) per 1,000 persons, respectively, with the most affected group being young and school-age children. Conclusions: Young and school-age children populations are potential targets for influenza vaccination in Indonesia.

Background

Seasonal influenza has been reported to have a disproportionate impact upon morbidity and mortality in developing countries. One study estimated that 90 million new cases of acute lower respiratory tract infections and 28,000-111,500 deaths were attributable to seasonal influenza in children younger than 5 years old in 2008, with 99% of these deaths occurring in developing countries.¹ Another study estimated that 291,243-645,832 seasonal influenza-associated respiratory deaths occur annually worldwide.² In addition, Southeast Asia was found to have the second highest estimated seasonal influenza associated mortality rate (3.5-9.2 deaths per 100,000 individuals), after Sub-Saharan Africa.² These estimates suggest that influenza is an important public health problem in lower- and middle-income countries, including Indonesia.

Implementation of influenza prevention and control programs in Indonesia has been
hindered by many factors, including the sparsity of data to guide policy makers. Although influenza vaccination of priority groups has been recommended in all countries by the WHO, the Indonesian government has not added influenza vaccination to the national immunization program. Baseline disease burden data are needed to assess the potential impact of influenza vaccination programs and other preventive measures. In Indonesia, information currently available on the morbidity and burden of influenza is from six surveillance studies\(^4\)\-\(^9\) conducted during 1999 to 2016. These studies were mainly hospital-based and/or did not utilize a population-based approach. A recent population-based study of influenza morbidity in Indonesia focused on severe hospitalized influenza cases.\(^7\) Hospital-based studies underestimate the population incidence of the spectrum of disease and often capture patients from different areas, leading to difficulty in defining the population at risk. It is estimated that mild cases of uncomplicated influenza, of which most are not medically attended or lead to hospitalization, contribute to 98.7% of all estimated influenza-associated illness,\(^10\) potentially leading to economic losses due to absenteeism at schools and workplaces. Thus, there is a need for population-based studies in Indonesia to estimate influenza disease burden in the community that also take into account health care utilization.

To our knowledge, none of the previous studies in Indonesia estimated the burden of influenza outside the hospital setting within a well-defined community area or among a population at risk. The objective of this study was to describe the epidemiology of influenza by estimating the population-based incidence of influenza in two small, well-defined communities before, during, and after the 2009 H1N1 pandemic. The study aimed to measure the total and age-specific morbidity of influenza in the community while addressing health care utilization.
Methods

2.1 Study location and period

This study was conducted in two peri-urban areas of Bandung District, West Java, Indonesia (Figure 1). The sites were selected as a part of the Zoonotic Avian Influenza-Human Animal Interface Project, following reports of human infections with highly pathogenic avian influenza A (H5N1) virus with severe lower respiratory tract disease from these sites who were managed at Dr. Hasan Sadikin General Hospital, Bandung in 2008.

The study areas are located on a river basin surrounded by volcanic mountains with cooler temperatures (annual average of 23.6°C/74.5°F) compared to other Indonesian cities, at an elevation of 768 m above sea level. This region has a tropical climate with annual average rainfall ranging from 1,000-3,500 mm. In 2009, the total population in the two subdistricts was 163,024, with a total area of approximately 21 km². The age distribution in this population is comparable with Indonesia in general, with 69% of the population aged between 16-65 years. Bandung District has a reported life expectancy of 69.4 years (2010), similar to the national life expectancy (70 years), but slightly higher than the average for West Java (66.6 years). Stunting in children aged <5 years is 25% (2011), higher than the national average of 19%. There are three government-funded community public health centers (puskesmas) serving the area—in addition to private clinics—with a medical doctor to population ratio of approximately 1 to 25,000. Puskesmas provide subsidized health care services, mostly for low-income patients. During the study period, the recent Indonesian national health insurance policy had not been implemented; so most healthcare expenditures were paid out of pocket. There are no published national data on influenza vaccination uptake or in these communities, but it is assumed that less than 1% of the population are vaccinated for influenza annually.
2.2 Data collection and quality control

Surveillance for influenza was conducted among persons with influenza-like illness (ILI) from October 2008 to September 2011 at three puskesmas: two in Cileunyi Subdistrict and one in Soreang Subdistrict. Dedicated, trained study physicians were assigned to screen and enroll patients with signs and symptoms of ILI. ILI was defined as having a fever (measured temperature of >37.5°C) or history of fever or feverishness and antipyretic treatment and having either cough or sore throat. Only subjects residing within the study area, as proven by ID card, and willing to provide written informed consent were eligible for this study. Basic demographic and clinical information from all subjects were recorded using standardized pre-tested case report form. Nasal and oropharyngeal swabs were collected from all subjects with ILI and transported to Dr. Hasan Sadikin General Hospital Laboratory for influenza virus testing. Trained nurses conducted home visits at 2 weeks post enrollment, collecting information using a standardized pre-tested questionnaire on clinical outcomes, household, environmental risk factors, and house geo-coordinates which were recorded by a handheld GPS receiver. For seasonality analysis, secondary data on weather parameters (rainfall, relative humidity, maximum and minimum temperature) were collected during the study period from Bandung city BMKG (Indonesian Geophysics, Climatology, and Meteorology Agency), agency responsible for weather and climate monitoring in Indonesia.

To measure the size of the population at risk or study denominator, we conducted a census of the population within the administrative areas served by the three puskesmas. Four hundred forty-eight trained, local community health workers (kaders) used standard census forms to obtain basic household demographic data, including household size and age group of all household members, which was classified into five categories: (a) <5 years old, (b) 5-15 years old, (c) 16-50 years old, (d) 50-65 years old, and (e) >65 years
old. A field coordinator performed quality control audits and identified errors or missing values in the survey forms. Incomplete forms were returned to the kaders for verification and corrections. After the population lists and addresses were validated, trained field surveyors conducted door-to-door visits to verify addresses and recorded all house geo-coordinates using handheld GPS receivers. All of the data-cleaned forms were entered into a secured web-based system by a dedicated data entry operator.

2.3 Statistical analysis

The seasonality of influenza was illustrated through a time series graph, defining cases by virus type, influenza A subtype, and age group, overlaid by weather data (rainfall, relative humidity, maximum and minimum temperature) throughout the study period (Figure 2).

Age group susceptibility was shown through a time series graph to show the age distribution of influenza positive cases by virus type and influenza A subtype throughout the study period (Figure 3). Population-based cumulative incidences of symptomatic influenza A and B virus infections were estimated for 2009, 2010, 2011, and stratified by age. Adjustments were made for age group specific variation in Community Health Care Utilization (CHCU) and for direct standardization to census data. For our CHCU adjustment, data on percentage of the population with ILI seeking medical treatment at a community health center for each age group was from an unpublished study by Dwi Agustian et al. This multiplier was applied to calculate the adjusted age group specific number of cases (adjusted numerator). The age group categories used followed the classification as defined in census data. The adjusted numerator was calculated by dividing the number of cases for each age group by CHCU percentages and standardized for 1,000 persons. For all calculations of annual incidences, the same number of population at risk (denominator) for each age group, enumerated by the census, was used with the fixed/closed cohort population assumption during the study. The confidence intervals were calculated using
the WHO method.  

2.4 Laboratory methods

Combined throat and nasal swabs from each subject were transported at 4–8°C in a Virus Transport Medium (Beckton-Dickinson, NJ, USA) to the Research Laboratory in Dr. Hasan Sadikin General Hospital. A one-step multiplex real-time RT-PCR assay was used for influenza A and B viral RNA detection, using primer and probes in two separate assays by standard protocols. The first assay was comprised of specific primers and probes for matrix (M1) gene (Influenza A) and host glyceraldehyde-3-phosphte dehydrogenase (GADPH) gene (Influenza B). The second assay was comprised of primers and probes specifically for the H1, H3, and H5 hemagglutinin (HA) gene regions for influenza A virus subtype detection. The probes were labeled with three fluorescent dyes (FAM, HEX, and Cy5, with emission wavelengths at 518, 556, and 667 nm, respectively). Positive specimens for influenza A were further subtyped for H1N1pdm09, H3, and H5 using the CDC protocol. Positive specimens for influenza B were further characterized as Yamagata-like and Victoria-like viruses by RT-PCR using the WHO protocol.

Results

From October 2008 to September 2011, study physicians identified and enrolled 3,305 ILI patients (Table 1). Overall, 456 (14%) patients tested positive for influenza viruses, including 10.9% (359/3,305) influenza A and 2.9% (97/3,305) influenza B. Further subtyping for influenza A yielded 9 (2.5%) H1N1, 157 (43.7%) H1N1pdm09, 193 (53.8%) H3N2, and none for H5N1 virus. The majority of ILI patients were less than 15 years old with high school education or less. We found relatively higher than expected frequency of sneezing reported among influenza positive subjects (25%-45%). Only six out of 3,305 ILI subjects were hospitalized, of which only one person had laboratory-confirmed influenza
Figure 2 illustrates the pattern of seasonality and circulation of different types/subtypes of influenza viruses. Five peaks of greater than 15% influenza positive occurred, with influenza activity identified every month except between December 2009 to February 2010. This window of zero detectable influenza activity occurred just after the first wave of the 2009 H1N1 pandemic. Through early 2009, seasonal influenza A(H1N1) virus was identified in our study population and later replaced in 2010 by influenza A(H1N1)pdm09 virus. Each peak of higher influenza virus activity was predominantly driven by a particular influenza A subtype or influenza B.

In Figure 3, influenza activity is shown by type, influenza A virus subtype, and age group, by 6-month intervals. In the first 6-month interval, there were relatively more A(H3N2) virus infections occurring in younger age groups; while in the second interval, adults aged 51-65 years had the highest percentage of ILI subjects with A(H3N2) virus infections. However, during the last interval, the percentage of A(H3N2) virus in the 51-65 years old group decreased, while increasing again in the younger age groups. In the second interval, A(H1N1)pdm09 virus infections emerged, occurring more in the school age group (5-15 years old); while during the two last intervals of study (October 2010-March 2011 and April-September 2011), older adults were more impacted. B Yamagata-like virus had a higher infection percentage in school-age children in the first study interval, with elderly more impacted during the second interval.

During the study period, the estimated annual cumulative incidence of symptomatic influenza A virus infections varied from 1.6 to 2.3 per 1,000 persons and the annual cumulative incidence of symptomatic influenza B virus infections ranged from 0.1 to 0.7 per 1,000 persons, after adjusting for community health care utilization percentages. Children aged <5 years were most affected, with estimated annual incidence of 6.3 to
10.6 and 0.4 to 4.3 per 1000 persons for symptomatic influenza A and B virus infections, respectively. Persons aged >65 years had the lowest estimated annual incidence for both influenza A and B (Figure 4). The number of influenza cases adjusted by community health care utilization for ILI and population size (adjusted numerator) is presented in Table 2. The estimated adjusted annual cumulative incidence of ILI, influenza A, and influenza B by age group is presented in Table 3.

Discussion

The seasonality of influenza we documented in West Java, Indonesia during 2008-2011 showed a typical pattern for a tropical region—with year-round influenza virus circulation, sharp short-spikes, and large variation of peak timing—and is consistent with previous studies by Beckett et al between 1999-2003 and Kosasih et al during 2003-2007. Peaks in influenza incidence coincided with higher precipitation months which generally occurred between December to March, except for July-August 2009 when A(H1N1)pdm09 virus emerged. Periods of high influenza activity ranged from 2 to 6 months, followed by low influenza activity for 2 to 4 months. Every year, we observed two or three peaks of increased influenza activity, with each peak typically predominated by a different virus and variability in the age group with the highest proportion of influenza positives from season to season. This variation could be due to differences in immune susceptibility by age, introduction of bias from differential health seeking behavior by age group or seasonal changes in health care seeking behavior, or chance variation due to smaller sample size when stratified by season and age group. However, a previous community cohort study in Vietnam also reported differences in impacted age groups by year. This continuous and dynamic year-round circulation of influenza viruses in West Java suggests that the best timing of influenza vaccination is not easily defined; therefore, if a
national influenza vaccination program is implemented in Indonesia, one strategy is for influenza vaccination to begin as soon as influenza vaccine is available each year. One study suggested that influenza vaccination should be given before the Hajj, \(^{16}\) since thousands of people travel from Indonesia to the Hajj annually and influenza vaccination is required for Hajj pilgrims at entry into Saudi Arabia. However, the dates of the Hajj pilgrimage vary from year to year, adding practical challenges to this implementation.

Alternatively, since increases in influenza activity coincide with high precipitation months, influenza vaccination could be implemented before the start of the rainy season, usually around October or November.

We observed that following the introduction of the 2009 H1N1 pandemic virus in Indonesia, overall influenza virus activity in the population dropped significantly and was not detectable in our study during January 2010. This was despite the relatively higher precipitation levels during that interval (Figure 2). Other studies conducted during the same period, including a study in East Java, Indonesia by Yamaoka et al\(^4\), in rural Thailand by Baggett et al\(^{17}\), in an urban Kenya by Katz et al\(^{18}\), and in Ha Nam District, Vietnam by Horby et al\(^{15}\), also showed a similar pattern of low seasonal influenza A and B virus activity after the first 2009 H1N1 pandemic wave. This suggests that the first wave of the pandemic might have led to a disruption of influenza virus activity afterward; not only in Indonesia, but also in other tropical climate countries. We also observed displacement of seasonal influenza A(H1N1) virus by the emergence of influenza A(H1N1)pdm09 virus in mid-2009.

To our knowledge, there are no data on the population-based incidence of uncomplicated influenza in Indonesia. The estimated annual incidence of influenza A in the community varied from 1.6 to 2.3 per 1,000 persons during the 3 years of our study. The CHCU rates
we used to adjust the incidence were comparable with the estimated medically-attended rate among cases of influenza from a study in South Africa. The incidence of influenza in our study was low compared to the influenza incidence based among ambulatory patients in sub-tropical China (4.1 to 19.2 per 1,000 population in 2008 and 2009), Kenya (13.6 to 23 per 1,000 person-years in 2007 to 2010), and Bangladesh (130 to 170 per 1,000 person-years in 2009 and 2010). The lower influenza incidence in our study might reflect differences in the study populations (health seeking behavior, demographics, nutrition, and medical risk factors) and health system factors (health care accessibility), or study design and methodology (inclusion criteria, case definition, laboratory testing, and estimation approach).

We found children younger than 5 years old to be the most affected age group for both influenza A- and B-associated illness, with estimated incidence of 7 to 10.6 per 1,000 person-years and 0.4 to 4.3 per 1,000 person-years, respectively. The exception was during 2010, when school-age children (6-15 years old) had the highest estimated annual incidence of influenza B. Other studies in Indonesia and Kenya reported that the highest incidence of hospitalized influenza-associated severe acute respiratory infection was in children under 5 years old. Our finding based upon virologic testing that showed young children were most affected by influenza is consistent with a community cohort study that utilized serological testing for influenza virus detection. School-age children had the second highest influenza incidence, similar to what was reported in a community cohort study in Vietnam. One study indicated that children aged 5-17 years are a driver of influenza A virus epidemics and that influenza vaccination of this group may contribute to reducing the overall impact upon the community.
This study showed a trend of decreasing annual cumulative incidence with increasing age for both influenza A and B cases (Figure 4). The age-specific influenza incidence trends did not change when we performed stratified analyses by influenza A virus subtype, influenza B, or study sites. Persons older than 65 years old had very low estimated influenza incidence compared to younger age groups (Table 2), consistent with the findings of an influenza surveillance study conducted during a similar period in East Java, Indonesia. The small number of older adult subjects enrolled in this study, which appeared to be proportional with the Indonesian population age structure, implied a higher uncertainty or random error margin. It is possible that the small number of infections we detected in older adults was because elderly persons may not always seek medical care or may not manifest fever with influenza when presenting for primary care and would have been missed by our ILI case definition, so we would have underestimated influenza disease burden in the elderly population. To perform sensitivity analysis, we also calculated the annual incidence among elderly by using a lower CHCU percentage among elderly (21.7%) as reported from another Indonesian study, but the incidence of influenza among elderly was still the lowest among all age groups (Supplementary Table 1).

There were several limitations of this study. It is known that most persons with influenza do not seek medical care and estimates of disease burden in the community, based on passive surveillance case detection, need to account for health care utilization and other factors such as subject refusal. We adjusted our incidence estimates to account for health care utilization of persons with ILI to account for this bias. However, the health care utilization percentage used for adjustment in this study was derived from an unpublished survey that was conducted after our study (2014) with limited sample size. In
2014, the National Health Security program (JKN) for Indonesian universal health care was launched that increased health care utilization in general, including for persons with ILI. The three clinics that participated in ILI surveillance were open 5 days per week and it is possible that some persons with ILI were missed if the clinics were open 7 days per week. Therefore, our adjusted incidence estimates likely underestimate the incidence of ILI and influenza in the community. Moreover, health care utilization is dependent on access to medical services, which may vary by location, while we assumed the same level for the whole study area. Therefore, the adjustments made in this study might not fully address health seeking behavior that differs temporally and geographically. In addition, the confidence intervals of the incidence estimates were calculated by the WHO method, which does not address uncertainty in the proportion of ILI cases that present to included clinics, and could lead to further imprecision of the incidence estimates. We also did not assess asymptomatic influenza virus infections, and since enrollment and testing for influenza required meeting the ILI case definition, symptomatic individuals with influenza virus infection without ILI and who sought medical care were not captured. Therefore, our estimates of symptomatic influenza incidence underestimate the overall burden of influenza in the community. The refusal rate was very low, but we did not record the number and the characteristics of the refusal group and were unable to adjust for the percentage of persons who decline to participate in the study; we assumed refusals occurred similarly across age groups. To estimate the population at risk, we assumed a fixed cohort population, which may have changed over the study period. Overall, the study population in these two areas was relatively small and might limit the generalizability of findings to other areas of Indonesia.

Conclusions

The mean annual incidence of influenza A and B, adjusted for health care utilization, was
1.6 (95% CI 1.3-2.0) and 0.7 (95% CI: 0.5-1.0) per 1,000 persons, respectively, with the most affected group being young and school-age children in West Java, Indonesia. Therefore, these populations are potential targets for influenza vaccination. This study reiterates the importance of pediatric populations in lower- and middle-income countries as a target for influenza vaccination and other prevention measures.
