Genomics offered the promise of transforming antibiotic discovery by revealing many new essential genes as good targets, but the results fell short of the promise. While numerous factors contributed to the disappointing yield, one factor was that essential genes for a bacterial species were often defined based on a single or limited number of strains grown under a single or limited number of in vitro laboratory conditions. In fact, the essentiality of a gene can depend on both the genetic background and growth condition. We thus developed a strategy for more rigorously defining the core essential genome of a bacterial species by studying many pathogen strains and growth conditions. We assessed how many strains must be examined to converge on a set of core essential genes for a species. We used transposon insertion sequencing (Tn-Seq) to define essential genes in nine strains of *Pseudomonas aeruginosa* on five different media and developed a statistical model, \textit{FiTnEss}, to classify genes as essential versus nonessential across all strain–medium combinations. We defined a set of 321 core essential genes, representing 6.6% of the genome. We determined that analysis of four strains was typically sufficient in *P. aeruginosa* to converge on a set of core essential genes likely to be essential across the species across a wide range of conditions relevant to in vivo infection, and thus to represent attractive targets for novel drug discovery.

Significance

Current antibiotics are increasingly ineffective due to rising resistance, and antibiotic discovery campaigns frequently fail. One key factor in effective antibiotic discovery is knowing whether a target’s function is essential in a bacterial species. We present a general paradigm for comprehensively identifying the core essential genome of clinical pathogens to identify candidate drug targets. We applied the paradigm to *Pseudomonas aeruginosa*, a priority antibiotic-resistant pathogen, by performing genome-wide genetic selection studies across a diverse set of clinical isolates and infection-relevant growth conditions (serum, sputum, and urine). We identified 321 core essential genes that constitute a high-priority list of candidate targets for drug discovery. The strategy should be applicable to define the core essential genome for most clinical pathogens.

Another issue is that some targets may be essential only under certain growth conditions (i.e., conditional essentiality) (6). Given the variable environments encountered by bacterial pathogens in laboratory media and different infection types (i.e., blood, urine, lung, abscess infections), genes essential in artificial laboratory growth conditions need not be essential during human infection. This concept has been illustrated in the ongoing debate of whether fatty acid biosynthesis, specifically the type II fatty-acid synthesis (FASII) pathway, is essential in gram-positive bacteria during infection (7). Although the pathway is essential under conventional in vitro laboratory conditions, Brinster et al. (8) challenged its essentiality in vivo by showing that several gram-positive pathogens could be rescued in vitro by the addition of exogenous unsaturated fatty acids.

All current antibiotics to date target essential functions in the bacterial cell. The sequencing of the first bacterial genome in 1995 (1) offered the hope of revolutionizing antibiotic discovery by revealing the breadth of genes that could be mined for antibiotic targets, enabling genome-wide screens to identify essential genes in a given bacterial species and paving the way for chemical screens to find new antibiotics inhibiting these essential targets. However, this revolution has, to date, failed to materialize. Several factors contributed to the disappointing yield of new antibiotic candidates. These include the challenge of overcoming the impermeable membrane and efflux pumps in bacteria, which have made it difficult to translate inhibitors found in biochemical assays into compounds with whole-cell activity; the need for improved chemical libraries to provide better starting points for chemical optimization against bacteria; and the focus on searching for broad-spectrum agents with activity against a range of bacterial species (2, 3).

Another contributing factor, however, has been the erroneous determination of target essentiality, resulting in the pursuit of inhibitors of targets that are either not essential at all in the species or not essential in a subset of strains. Indeed, two major studies experienced this challenge, with one study describing “genomic blind spots” involving targets that were erroneously thought to be essential based on the limited pathogen genomic data available at the time, but were actually nonessential in additional subsequently tested strains (4, 5). As a result, some inhibitors of targets thought to be essential failed to have good activity against the full range of relevant pathogen strains (2, 3).
acids and that a mutant of Streptococcus agalactiae in which numerous FASII genes had been deleted could be grown in both human serum and septicemia mouse infection models, presumably because of its ability to scavenge host fatty acids. The concept of conditional essentiality is similarly illustrated in the notable example of an inhibitor series that was developed to have potent in vitro activity against Mycobacterium tuberculosis, but later found to have no activity in a mouse tuberculosis model because the inhibitor’s activity was dependent on growth in glycerol, the carbon source present in a standard laboratory medium but not the source utilized by M. tuberculosis during infection (9). These examples clearly highlight the value of defining targets relevant to in vivo infection, and not simply to in vitro conditions. At the same time, we note that targets that may be essential under some, but not all, relevant in vivo conditions may provide novel approaches to infection site-specific agents.

Given the challenges of genomic blind spots and conditional essentiality, we propose that antibiotic discovery could be improved by focusing on “core essential genes,” by which we mean genes that are essential across virtually all strains of a pathogen species and all relevant growth conditions. We therefore sought to develop a robust paradigm for defining the core essential genes of a bacterial species. We focused on Pseudomonas aeruginosa, a clinically significant pathogen that is a major cause of bacteremia as well as pulmonary and urinary tract infections, with high mortality rates (10–12) and for which there is the greatest need for new antibiotics. Due to its ability to evade current antibiotics or develop resistance, P. aeruginosa clinical strains are increasingly resistant to all current antibiotics (13, 14). The WHO has recently classified P. aeruginosa as a priority pathogen in need of research investment and new drugs (15). Alarming, only one in five antibacterial drugs succeed in clinical trials (16), and of the 42 potential antibacterials in development as of 2018, only two have expected activity against P. aeruginosa, with only one of these having a new mechanism of action (https://www.pewtrusts.org/en/research-and-analysis/articles/2016/12/tracking-the-pipeline-of-antibiotics-in-development).

In pursuit of a general strategy to define a pathogen’s core essential genome, we examined two fundamental questions. First, how accurately can the core essential genome be identified based on the assumption that one strain under one specific condition? Second, how many strains must be examined to converge on a set of core essential genes that are likely to be essential under conditions relevant for infection, and thus may be good drug targets? We addressed this question by using transposon insertion sequencing [Tn-Seq; also abbreviated as TIS, INseq, HITS, or TraDIS (17–21)] to perform genome-wide negative selection studies on libraries of transposon-insertion mutants under different growth conditions, with the distribution of transposon insertions determined by sequencing the pool of strains. Genes that are important for optimal growth under a specific growth condition can be identified, because the corresponding mutants containing disrupting transposon insertions in these genes will be significantly depleted from the pool of all possible mutants. These methods have been applied to the two commonly studied reference laboratory strains of P. aeruginosa, PA14 and PA01, with varying numbers and identities of essential genes (22). Here, we applied this method to PA14 on Luria–Bertani (LB) medium and compared the essential genome determined from this single strain on a single laboratory-based medium with eight other diverse strains of P. aeruginosa under five different growth conditions. The strains comprised isolates from various human infections (including pulmonary, urinary, blood, wound, and ocular) and one environmentally isolated strain, while the growth conditions comprised three media intended to simulate the conditions of human infection (spumut, serum, and urine) and two laboratory-based media (LB and M9 minimal media). We further developed a simple statistical method, called FiTnEss (Finding Tn-Seq Essential genes), that maps measurements of fitness of individual transposon mutants onto a binary classification of essential or nonessential with user-defined levels of stringency. We applied FiTnEss to the Tn-Seq data from all strain and medium combinations and defined a set of 321 core essential genes, which represent 6.6% of the genome, that constitute a high-priority list of candidate targets for drug discovery against this important pathogen. Finally, we calculated that as few as four individual strains could be examined in combination to approach a plateau of core essential genes across a given species.

Results

Transposon Mutagenesis, Sequencing, and Mapping of Transposon Insertions. We chose strains from a collection of 130 clinical P. aeruginosa isolates obtained from various sources (Materials and Methods). We performed whole-genome sequencing on the collection and mapped the isolates to a phylogenetic tree formed by 2,560 P. aeruginosa genomes in the National Center for Biotechnology Information (NCBI) Genome database. We also tested a subset for their ability to be efficiently mutagenized by the Himar1-derived transposon MAR2xT7 (23–25). We selected the MAR2xT7 transposon because it is engineered to reduce polar effects that can occur when transposon integration into a nonessential gene disrupts the transcription of a downstream essential gene (because it contains a gentamicin resistance cassette that lacks a transcriptional terminator downstream, and thus allows downstream transcription from the gentamicin resistance promoter).

Based on this information, we focused on nine strains that represented five different infection types (blood, urine, respiratory, ocular, and wound), with each strain representing a different branch of the dendrogram (NCBI; Fig. 1A). The genomes of these nine strains varied from 6.34 to 7.15 Mbp.

We constructed transposon libraries by performing tripartite matings of these nine P. aeruginosa strains with Escherichia coli donor strain SM10 carrying an episomal MAR2xT7 transposon (24) and E. coli strain SM10 carrying an episomal hyperactive transposase that results in efficient integration at the dinucleotide sequence “TA” (26) (SI Appendix, Fig. S1). Separating the transposon mutants selected on each medium in duplicate, yielding 10-fold more transposon mutants than possible insertion sites. The media types included rich (LB) and minimal (M9) laboratory media, to provide the boundaries (extremes of growth conditions) for essential gene identification, and three media intended to resemble infection site fluids: FBS, synthetic cystic fibrosis sputum (SCFM) (27), and urine. We mapped the transposon-insertion sites to the corresponding reference genomes for each strain.

In all, we created 90 Tn-Seq datasets (nine strains grown on five media, performed in duplicate), with an average number of mapped reads of ~107. Reads at each TA site were highly concordant between replicates, with a mean R² = 0.98 (Dataset S1).

Visual inspection readily identified examples of genes that were variably essential under different growth conditions for a certain strain, illustrating the conditional essentiality of some genes (Fig. 1B). For example, the thiamine synthesis genes thiD and thiE showed few insertions in M9 minimal medium, which lacks thiamine, but an abundance of insertions in rich LB medium, indicating their essentiality in M9 but not LB medium.
Variability is also seen for the hemL gene under different growth conditions. We similarly saw examples of genes that were variably essential in different strains under the same growth condition. For example, the pilY1 gene did not tolerate insertions in strain BW1013, but readily tolerated insertions in the other eight strains, when grown on LB medium, highlighting the genomic plasticity of P. aeruginosa (Fig. 1C).

To optimize our accuracy in calling genes essential or non-essential, we removed from our analysis three classes of TA sites that can lead to technical errors. These classes include (i) non-permissive insertion sites consisting of the sequence (GC) GNTANC(GC), which was recently reported to be intolerant to Himar1 transposon insertions in M. tuberculosis (28) and which we confirmed is also intolerant in P. aeruginosa; (ii) non-disruptive terminal insertions within 50 bp of the 5′- and 3′-gene termini (a distance we optimized empirically), which can nevertheless result in the expression of a functional, albeit truncated, version of the corresponding gene product (29); and (iii) insertion sequences at which genomic sequences flanking a TA site were not unique and could not be accurately mapped (Materials and Methods and SI Appendix, Fig. S2). In total, we removed 16,499 of 81,328 TA sites (20%) in PA14, which resulted in our inability to assess 150 genes in PA14 (2.5%). The inability to assess the essentiality of genes that contain zero TA sites (30) was not unique and could not be accurately mapped (Materials and Methods and SI Appendix, Fig. S2). In total, we removed 16,499 of 81,328 TA sites (20%) in PA14, which resulted in our inability to assess 150 genes in PA14 (2.5%). The inability to assess the essentiality of genes that contain zero TA sites (30) was not unique and could not be accurately mapped (Materials and Methods and SI Appendix, Fig. S2).

**FitnEss: A Statistical Model to Identify Essential Genes.** We next sought to perform a comprehensive and quantitative analysis of the 90 Tn-Seq datasets. While various methods exist for analyzing Tn-Seq data (17, 31–33), they differ in their complexity and their stringency for calling a gene as essential. We thus developed a simple model and method (FitnEss) for identifying essential genes from Tn-Seq data that required minimal assumptions and had good predictive power. The important features of FitnEss are that (i) it evaluates genes (rather than individual TA sites or stretches of TA sites) and (ii) it uses a simple two-parameter model to capture all of the salient features of the data (with the simple model yielding greater statistical power).

FitnEss assumes that the number of reads observed at a particular TA site in a gene depends on the fitness of loss-of-function mutant in the gene. We found that the distribution of the number of TA sites per gene is bimodal, with presumed nonessential genes on the right and essential genes on the left (SI Appendix, Fig. S3A). The distribution of nonessential genes can be well fit by a model in which the read counts at TA sites in a gene follow a geometric distribution with probability pg, with 1/pg drawn from a log-normal distribution. This model requires only two parameters: μ (the mean fitness for nonessential genes, as reflected in the mean reads per TA site in a gene) and σ (the variance of the fitness for nonessential genes). We calculate μ and σ for each individual Tn-Seq dataset, based on nonessential genes and then apply it to the entire dataset. Because the validity of the model depends on our estimates of μ and σ based on nonessential genes, we are conservative in including nonessential genes: We take only genes from the extreme right side of the distribution (top 75% of genes with the most reads, with 10 TA sites).

This model requires one other assumption, that the fitness distribution does not depend on gene size or number of TA sites contained in a gene. Rephrased, the model assumes that the number of reads at each TA site is independent of the number of TA sites in a gene. We tested the validity of this assumption. Because detection power for a gene depends on the number of TA sites in the gene (SI Appendix, Fig. S3B), we compared the distributions of reads at randomly sampled TA sites, allowing us to compare similar numbers of sites in genes of different size. We found that the numbers of reads at randomly sampled TA sites were independent of the number of TA sites in a gene (SI Appendix, Fig. S3D), confirming the validity of our assumption.

Using the two parameters (determined individually for each dataset), we then constructed a theoretical “nonessential” distribution for each gene size category within each corresponding dataset and calculated the probability (P value) of a given gene coming from this nonessential distribution. To vary the stringency with which we called essentiality, we applied two different levels of multiple testing adjustment: one with maximal stringency to offer the highest confidence set of essential genes [family-wise error rate (FWER)] to identify genes with no or very few sequencing reads and one with high stringency yet slightly relaxed [false discovery rate (FDR)] to identify genes that are statistically significant yet contain a low number of reads. Genes with an adjusted P value <0.05 in both replicates were predicted to be essential (Fig. 2 A and SI Appendix, Additional Methods and Results). Virtually all maximal stringency calls are expected to be true essential genes, while among the high-stringency set, a small number of false-positive predictions are expected.
The gray histogram is the essentiality predictions (identified as nonessential in LB medium, axis indicates the TA insertion no. 20 performance based on actual deletion mutant growth profiles.

To validate PNAS vol. 116 C | May 14, 2019 is 91% or 100% (depending on the classification of in-

values that fall at the boundary drawn to and predictions for all 90 datasets to identify the core essential predictions on a set of conditionally essential (left) to 3

Validation of Fig. 2. (A) FITnEss prediction for ilvC in urine. The graph histogram is the actual distribution of Tn-Seq reads for all genes with 18 insertion sites in PA14 grown in urine, the black line is the theoretical distribution calculated by FITnEss, and the red line is where ilvC falls at the far left (i.e., essential) of the bimodal distribution. (Inset) Read numbers at useable (red) and removed (blue) TA sites are shown; a black tick on the x axis indicates the TA insertion site location within the gene, and the gene is presented 5′ (left) to 3′ (right). (B) FITnEss essence predictions (Left; nonessential, high-stringency ess-

ential, and maximal stringency essential predictions are displayed as dark green circles, light green circles, and blank spaces, respectively) of five re-

presentative gene deletion mutants from PA14; actual mutant growth mir-

rored predicted growth on five media (Right). The red box identifies the absence of growth of ΔilvC (the deletion mutant highlighted in A), thus experimentally confirming its essentiality on urine. The full growth profiles of 23 gene deletions can be found in SI Appendix, Fig. S4. (C) Summary of FITnEss performance based on actual deletion mutant growth profiles. Gene-medium instances are indicated in parentheses; and red and green boxes highlight false-positive and false-negative rates, respectively.

Validating FITnEss Using Strain PA14. To validate FITnEss’s approach to predicting gene essentiality, we compared its predictions with actual viability and growth measurements for a set of PA14 mutants in which we cleanly deleted particular genes of interest. We created clean deletion mutants corresponding to 20 genes that FITnEss identified as nonessential in LB medium, but were essential in one or more of the other media, as well as to three control genes that were predicted to be nonessential in all media. We determined the positive and negative predictive values of FITnEss by growing the 23 mutants on the same five media as used in the original Tn-Seq experiments, for a total of 115 gene-medium combinations. Mutant strain viability was cate-

gorized as essential, intermediate, and nonessential using densitometry (<20%, 20–50%, and >50% relative to wild-type strain PA14 containing no transposons, respectively; Fig. 2B and C and SI Appendix, Fig. S4). Of the 35 combinations predicted to be essential by the maximal stringency criteria, 30 were indeed found to be essential and five were of intermediate growth. Importantly, no strains within this criterion were, in fact, non-

essential. By relaxing the stringency slightly to “highly stringent” 15 additional strain-medium combinations were predicted to be essential, eight of which were truly essential or of intermediate growth and the remaining seven were nonessential, corroborating our prediction that some false-positive predictions would be expected in this category. Of the 65 combinations predicted to be nonessential, none were found to be essential, but six were found to be of intermediate growth. In this limited dataset, FITnEss had a positive predictive value of 100% using maximal stringency and 86% using the high-stringency predictions (if intermediate genes are classified as essential). The negative predictive value of FITnEss is 91% or 100% (depending on the classification of in-

termediate genes). Notably, all three control strains behaved as predicted, growing on all media, despite our having chosen those control strains with P values that fall at the boundary drawn to distinguish essential and nonessential genes, further reinforcing the accuracy of this binary classification. All together, these results support FITnEss’s ability to accurately call essential and nonessential genes, and that FITnEss’s stringency can be varied based on user tolerance of false-positive versus false-negative predictions. Importantly, FITnEss correctly predicted gene essentiality despite the presence of a small number of mapped insertions in the primary Tn-Seq data of some genes, as exemplified in the case of the ilvC gene encoding ketol-acid reductoisomerase (Fig. 2A).

Defining the Core Genome. We first defined the core genome consisting of 5,109 protein-coding genes (genes present in all nine strains) using the orthogroup clustering software Synerclust (34). The size of the core genome defined by these nine strains is comparable to what has been previously described for P. aeruginosa [5,316 total genes (35)]. Of these genes, 4,903 were pre-

sent in a single copy with TA sites that allowed assessment by Tn-Seq; the remaining genes (86 multicopy genes in which reads could not be accurately mapped due to sequence homology and 120 small genes that do not have TA sites permissive to transpo

son insertion) could not be assessed (Dataset S2). The ac-

cessory genome within each strain (the genes that are not present in all nine strains) ranged from 655 to 1,369 genes.

Defining the Core Essential Genome. We then examined the FITnEss predictions for all 90 datasets to identify the core essential genes across the P. aeruginosa species (Table 1 and Dataset S3). If one examines only a single strain in a single medium, the number of essential genes varies widely between 354 and 727 genes, even when using the maximal stringency prediction (Table 1). If one examines only genes common to all strains (the core genome), however, the number of essential genes from strain to strain was much more tightly distributed (337–386 genes; SI Appendix, Fig. S5). In contrast, the number of essential genes in the accessory genome of each strain varied widely from 59 to 478 genes (SI Appendix, Fig. S5); interestingly, the number was roughly proportional to genome size (SI Appendix, Fig. S5).

When combining all nine strains across the five media and applying maximal stringency, we found that there are only 249 core essential genes (5.1% of the genome). This number is up to three-fold fewer than the number found for a single strain and medium. If we apply the slightly lower standard of high stringency (to allow for the possibility of some false-negative predictions in the data), an additional 72 genes (1.5% of the genome) are included, resulting in 321 genes. We define this set as the core essential genome.
To assess whether the core essential genome had reached a plateau, we calculated how the number of core essential genes decreases with additional strains (with strains added in 10,000 different random orders) (Fig. 3A). We found that the median across these trajectories typically plateaued after four strains, but that five strains would ensure 90% of all trajectories reaching a plateau defined as a <5% false-positive rate (Fig. 3B). Beyond the four strains, the maximum number of core essential genes declined by only 13 genes. These genes just failed to reach the essential P value threshold, suggesting that they were false-negative predictions (Dataset S4). If we were to include these 13 genes, the core essential genome would reach 334 genes. We also examined how the number of essential genes varied under different growth conditions. The numbers of genes that were essential in all nine strains in a single medium ranged from 412 to 439 genes, versus 334 genes under all growth conditions (Table 1).

We examined the identities and functions of the core essential genes. Of the 321 core essential genes, 263 correspond to cytosolic proteins, with 132 involved in metabolic pathways (50%) and 119 involved in macromolecular synthesis, including DNA replication, transcription, or translation (45%). Another 56 correspond to cytoplasmic membrane, periplasmic, and outer membrane proteins, with the majority involved in cell structure and division, involved in metabolism, or acting as transporters/chaperones (13, 12, and 26 genes, respectively). The remaining 12 of the 321 genes are completely uncharacterized (Fig. 4A and Dataset S5).

Conditionally Essential Genes. In addition to the core essential genes, the core genome contains conditionally essential genes that are essential in one or more, but not all, media. Sputum and M9 media had the highest number of conditionally essential genes (118 and 110, respectively), consistent with these being the most nutritionally depleted media. LB medium had 103 conditionally essential genes, while urine and serum had the fewest (69 and 91, respectively) (Table 1). While the numbers of essential genes required in each growth condition did not vary significantly from condition to condition, the actual gene identities did vary (Dataset S5). Importantly, we identified an additional 24 conditionally essential genes required for growth in all three infection-relevant media (serum, sputum, and urine; Fig. 4B) but not in both of the laboratory-based media (LB and M9). Several of these genes are involved in pyrimidine and purine synthesis and are not required in LB medium, suggesting that sufficient nucleotide intermediates may be present in LB medium to sustain growth in vitro but that these genes may be valid targets during in vivo infection.

When we applied multiple correspondence analysis to all sets of essential genes for every strain-growth condition, we find that, indeed, the vast majority of strains formed distinct clusters based on growth condition (SI Appendix, Fig. S6). Interestingly, one strain, PA14, an extensively used laboratory strain, was an outlier under two conditions, M9 and urine. In these two media, we observed that, compared with other strains, PA14 has more essential genes involved in the TCA cycle and oxidative phosphorylation. This behavior could be a consequence of PA14 being a laboratory strain that has adapted to laboratory conditions over a long period of time, perhaps providing a slight cautionary flag if attempting to extrapolate PA14 behavior to the species in general.

Contained within the sets of conditionally essential genes for each growth condition are genes that are essential only in a single medium, termed “unique conditionally essential” genes. Considering only the three infection-relevant conditions, while ignoring the laboratory conditions, sputum had 29, serum had 16, and urine had 17 unique conditionally essential genes. These unique conditionally essential genes carry the intriguing potential of becoming infection site-specific targets for infection type-specific antibiotics (e.g., a urine-specific antipseudomonal antibiotic) as long as their essentiality is not dependent on factors that are variable from patient to patient.

The essential genes unique to sputum consist mainly of biosynthetic pathways such as thiamine, pyridoxine, and tryptophan synthesis, with the former two cofactors being required for multiple cellular processes, including synthesis and catabolism of sugars and amino acids, and the latter requirement suggesting....

**Table 1. Number of essential genes in each strain-medium combination**

| Strain | Genes analyzed† | LB | M9 | Serum | Sputum | Urine | Strain essentials‡ |

§ Maximal stringency essential genes are shown; high-stringency essential genes are shown in parentheses.
that tryptophan levels in sputum may not be sufficient for growth (27). Similarly, urine-specific essential genes almost exclusively consist of genes involved in amino acid biosynthesis, specifically valine, leucine, and isoleucine pathways. Meanwhile, methionine and arginine pathways are essential in both urine and serum. The urine findings are consistent with the fact that these amino acids are among the least abundant in urine (30). However, despite the low abundance of proline and cysteine in urine, classical proline and cysteine biosynthesis genes are not essential, likely because alternative, functionally redundant synthesis pathways exist in *P. aeruginosa* for these amino acids (36, 37).

In contrast, most genes involved in amino acid biosynthesis are dispensable in serum, as are genes involved in heme biosynthesis (*pdxA,H* and *hemoAB,CD,E,F,H,I,L*), likely due to the ability to scavenge amino acids (38) and heme from free hemoglobin (39, 40) from serum. Interestingly, despite the nonessentiality of porphyrin genes in serum, genes involved in the formation and utilization of porphyrin-containing cytochrome *c* were uniquely essential in serum and no other media, including the cytochrome *c* biogenesis protein CcmH (PA14_57540), cytochrome *c1* (Cyt1; PA14_57540), the ubiquinol cytochrome *c* reductase (PA14_57570), and cytochrome *c* oxidase cbh3-type subunit I (CcoN; PA14_44370). *P. aeruginosa*’s respiratory flexibility is lost, as it becomes dependent on a single pathway.

To validate in vivo a strategy of targeting conditionally essential genes identified from our in vitro Tn-Seq experiments, we tested a set of PA14 deletion mutants for their ability to survive in different in vivo mouse models of *P. aeruginosa* infection. Using a neutropenic mouse model in which the bacteria are administered i.v., to test translation of the in vitro serum growth condition, we infected mice with six strains: wild-type PA14; three mutants containing deletions of metabolic genes predicted to be essential in serum, sputum, and urine but not LB medium (*pyrC, purH*, and *tpiA*, glycolysis; and *purH*, purine biosynthesis); one mutant containing a deletion in a gene predicted to be essential in serum and urine but not sputum (*argG*, arginine biosynthesis); and one mutant containing a deletion in a gene predicted to be conditionally essential in sputum alone but not serum or urine (*thiC*, thiamine biosynthesis; Fig. 5A). In concordance with their predicted conditional essentiality, the *pyrC*, *tpiA*, and *purH* mutants were significantly attenuated in the neutropenic mouse model with a three- to four-log reduction in total colony-forming units in the spleen 16 h postinfection. Interestingly, the *argG* mutant was not attenuated as predicted. To understand this discrepancy, we compared its growth on agar plates supplemented with mouse, bovine (which was used in the Tn-Seq experiments), or human serum. Indeed, the mutant was able to grow on mouse serum, but not on bovine or human serum, thereby explaining the lack of mutant attenuation in the mouse model, likely due to the higher levels of arginine available in mouse serum (42–44) (Fig. 5B). Finally, as predicted, the *thiC* mutant was not significantly...
attenuated in the neutropenic mouse model; it was, however, attenuated in an acute pneumonia mouse model, where the inoculum is delivered intranasally followed by colonization of the lungs, which is consistent with FitNEss predictions (Fig. 5C). Together, these datasets highlighted the tremendous differences required by \( P. \ aeruginosa \) in different microenvironments that could be exploited in the development of infection condition-specific therapeutics.

**Discussion**

Target-informed antibiotic discovery and development have been predicated on knowing which genes within a given species constitute good targets, with genomic technologies such as Tn-Seq paving the way for more comprehensive definition of essential targets. However, comprehensive genomic methods for defining essential targets, such as Tn-Seq, have largely been applied to only a single or a few bacterial strains under a single or a few growth conditions, with the implicit assumption that these results will apply to the entire species under infection-relevant conditions. Here, we sought to develop a general strategy for determining the core essential genome of a bacterial species and to examine how the number of essential genes varies among strains and growth conditions. We empirically determined that the analysis of essential genes among four diverse strains was sufficient to define the core essential genes in \( P. \ aeruginosa \).

Using Tn-Seq and a method of analysis, FitNEss, to establish the core essential genome of \( P. \ aeruginosa \), we determined that while a single strain has \( \sim 400 \)–800 essential genes, the core essential genome across all strains analyzed is \( \sim 321 \) genes, thus demonstrating the limitations in determining species specificity based on a single strain and/or single medium condition. Further, there are an additional 24 essential genes required for growth in the three infection-relevant media examined, which are non-essential in LB and M9 media. Finally, we find that there are \( \sim 15 \)–30 unique, conditionally essential genes for each of the infection-relevant media examined, with their corresponding biological pathways important for survival only within a particular host tissue environment; these genes may represent a unique set of targets for infection type-specific therapeutics, with the obvious caveat that their essentiality cannot be dependent on microenvironmental factors that vary widely from patient to patient. Interestingly, our study provides insight into differences in gene essentiality between \( P. \ aeruginosa \) and other characterized bacterial species such as \( E. \ coli \), which differ, for example, in genes required for ATP or fatty acid biosynthesis (45, 46).

Previous transposon mutagenesis studies of two common laboratory strains, PA14 and PAO1, have found varying numbers of essential genes, as reviewed by Juhas (22). These studies have predominantly focused on identifying genes refractory to transposon mutagenesis when bacteria are selected for growth on laboratory media, including LB, brain–heart infusion (BHI), and minimal media (24, 47–50), although recent studies have extended growth conditions to include sputum or sputum-like media (49, 50) in vitro. A comparison of all of these datasets combined revealed an intersection of only 109 essential genes common to all studies (Dataset S6). This low concordance is likely due to methodological or analytical differences between the studies. One way in which our study differs from the majority of previous studies is that we did not initially select transposon mutants on a rich (isolation) medium (i.e., LB medium) before selection on the condition of interest, thereby eliminating a bottleneck that prevents evaluation of genes essential in the isolation medium. By omitting the initial isolation step, we were able to identify 103 conditionally essential genes that are required in LB medium, but not in at least one of the other four media. In addition to these in vitro studies, in vivo Tn-Seq studies can be valuable in determining what genes are required for fitness in the context of an active infection (48); however, they also suffer from the problem of experimental bottlenecks that practically limit the ability to truly interrogate essentiality on a genome-wide scale. These bottlenecks include the required isolation step before inoculating into an animal and the depletion of mutants in vivo due to stochastic loss rather than a true fitness loss of the mutant itself (17).

Experimental methods for identifying gene essentiality have varied greatly through the years. Despite significant advances for defining fitness costs of gene disruptions on a genome-wide scale using sequencing (Tn-Seq), limitations persist. The inclusion (i) analysis of mutant behavior in pools where there can be both competition as well as \( \text{in trans} \) complementation, factors that can cause mutant growth in a pool to diverge from growth in isolation; (ii) transposon sequence insertion biases (28, 51); and (iii) polar effects on adjacent genes conferred by transposon insertion. These limitations prevented us from evaluating the essentiality of \( \sim 5\% \) of the genome and can technically lead to errors in assessing fitness and essentiality. We indeed found examples of discordance in our Tn-Seq data classified genes as essential even though mutants of these genes are available, albeit growth-defective, such as \( \text{hsf} \), \( \text{rpoN} \), and \( \text{gidA} \) (52–54). These cases could be due to FitNEss errors; alternatively, one must consider the possibility that these mutants have reduced fitness when grown in competition but not in isolation, or that reported mutants could contain compensatory mutants acquired in their construction that allow deletion of the gene of interest.

A major challenge to translation is translating measurements that quantify a continuum of fitness to a binary classification of essentiality versus nonessentiality to define the best antibiotic targets. Approaches can vary substantially, with different systematic errors and different tolerances for false-positive versus false-negative predictions (SI Appendix, Additional Methods and Results and Fig. S7). We therefore developed a Tn-Seq analysis pipeline, FitNEss, that balances false-positive and false-negative rates with the aim of accurately classifying gene essentiality, while providing two levels of stringency depending on one’s tolerance for false-positive versus false-negative predictions. We validated FitNEss using clean gene deletion mutants (Fig. 2 and SI Appendix, Fig. S4).

We used FitNEss to perform the binary classification of the 4,903 genes in the core genome that could be assessed across nine \( P. \ aeruginosa \) isolates. The great majority of core essential genes can be broadly categorized as being involved in metabolic pathways or macromolecular synthesis such as DNA replication, transcription, or translation. That the core essential genome is dominated by genes involved in macromolecular synthesis (i.e., nucleic acids, protein, cell wall) may explain, in part, why most current antibiotics seem to target this limited set of functions (i.e., fluoroquinolones, aminoglycosides, beta-lactams, respectively). Three recent gram-negative antibiotic candidates reported in the literature also target essential genes identified in this study [i.e., \( \text{tpID} \), \( \text{lepB} \), \( \text{msbA} \) (55–58)]. There has been greater reticence to target metabolic pathways, given concern over the ability of bacteria to scavenge nutrients from the host, thereby rendering their biosynthesis nonessential during infection. Indeed, we see variable requirements for metabolic genes in our identification of conditionally essential genes, such as a greater dependence on amino acid biosynthesis in urine rather than other growth conditions. We have, however, demonstrated that this conditional essentiality can, in fact, be exploited in vivo, as mice infected with the \( \text{pyrC} \), \( \text{tpIA} \), and \( \text{purH} \) mutants that are significantly growth-impaired on infection-relevant media have a drastically reduced bacterial burden in a systemic infection model. Further, the \( \text{thiC} \) mutant, found to be essential in M9 medium and sputum alone, was attenuated in an acute pneumonia model, yet was still virulent if introduced systemically, demonstrating variable metabolite levels in different infection sites in vivo and raising the possibility of infection site-specific therapeutics.
In summary, we suggest that a major factor in the failure of genomics to transform antibiotic discovery in the late 1990s to early 2000s was due not to a fundamental flaw with the concept of defining essential genes, but rather to challenges in implementing the approach, namely, defining essential genes based on limited information. Advances in genomic technologies now make possible studies on a much greater scale, allowing us to define essential genes in a way that overcomes previous shortcomings. Our work describes a general approach applicable to other pathogens, given the explosion in available bacterial genomes. While the number of strains required to reach a plateau in essential genes for different species may vary based on the genomic diversity of a species, the basic paradigm should apply broadly. Importantly, defining the core essential genome for selecting diverse strains across its phylogenetic tree will enable more effective discovery and development of much needed antibiotic therapeutics.

Materials and Methods

Strain Selection and Plasmid Construction. A genome tree report of 2,560 sequenced P. aeruginosa strains was downloaded from the NCBI (organism ID 187) and visualized with the Interactive Tree of Life (iTOL) tool (59). Nine strains were selected for genetic diversity and graciously gifted from various sources: PA14, 19660, and X13273 were obtained from Frederick M. Ausubel, Massachusetts General Hospital, Boston (60); BW1105, BW1103, and BW1105 were collected through the Brigham and Women’s Hospital Specimen Bank per a protocol previously described (61); BL23 was obtained from Bausch & Lomb (62); PS75 was obtained from Paula Suarez, Simón Bolívar University, Santenegia, Miranda State, Venezuela; and CF77 was obtained from the Boston Children’s Hospital (63). The pC9 containing a hyperactive transposase was derived from pSAM-DgM (48), and the pMAR containing the Himar1 transposon was derived from pMAR2x17 (24).

Transposon Library Construction and Sequencing. Recipient P. aeruginosa strains were prepared for mating as previously described (64). P. aeruginosa and midlog cultures of E. coli SM10(pC9) and E. coli SM10(pMAR) were collected by centrifugation, washed, and resuspended in LB medium. A total of 3 × 10^11 cfu were mixed in a 2:2:1 ratio of pC9/pMAR/recipient and collected by centrifugation. The cell mating mixture was resuspended to a concentration of 10^10 colony forming units of each transposon-integrating strain, and efficiencies were quantified by plating to LB-selective agar. Two hundred fifty milliliters of each medium containing 1.5% agar, 5 μg/mL gentamicin was prepared (27) were prepared. Pooled filter-sterilized urine and FBS (Thermo Fisher Scientific) were warmed to 55 °C and mixed with glycerol to a final concentration of 40%, aliquoted, and flash-frozen before storage at −80 °C. Matings were performed at least twice for each recipient strain, and efficiencies were quantified by plating to LB-selective agar. Two hundred fifty milliliters of each medium containing 1.5% agar, 5 μg/mL irgasan, and 30 μg/mL gentamicin was prepared in a Biodish XL (Nunc). LB and M9 minimal agar (US Biologicals) and synthetic cystic fibrosis medium agar (SCFM) (27) were prepared. Pooled filter-sterilized urine and PBS (Thermo Fisher Scientific) were warmed to 55 °C and mixed with a 5% agar solution (Teknova) to achieve a 1.5% final agar concentration. Five hundred thousand colony-forming units of each transposon-integrated strain was plated to each medium in duplicate and grown at 37 °C for 24 h (LB medium, PBS, and SCFM) or 48 h (urine and M9) before scraping and resuspending cells in PBS. Genomic DNA was isolated, and Illumina libraries were prepared using a custom method and primers described in SI Appendix, Fig. S1 and Dataset S7. Sequencing was performed with an Illumina NextSeq platform to obtain 50-bp genomic DNA reads.

Determining Essential Genes from Tn-Seq Data Using FiTeNs. All sequencing read count data and analysis files are available [https://data.broadinstitute.org/](https://data.broadinstitute.org/) fitens/ and on the NCBI Sequence Read Archive (65). The analysis pipeline, including sequencing summarization and the FiTeNs software, is freely available [https://github.com/broadinstitute/FiTeNs](https://github.com/broadinstitute/FiTeNs) (66). Genomes and annotations for each strain were obtained from [www.pseudomonas.com](http://www.pseudomonas.com) and [https://pathricbrc.org](https://pathricbrc.org). The core and accessory genomes were determined by gene clustering analysis across the strains tested using Synerclust (33). Illumina reads were mapped to each respective genome using Bowtie (68), utilizing the options for exact and unique read mapping. Reads potentially mapping to more than one location in a genome were discarded, and homologous TA sites were removed from analysis by searching the genome using custom scripts. TA insertion sites containing the sequence (GG)GNNANCGC(GG) were removed using custom scripts. Reads mapped to each TA site were tallied using scripts modified from a study by Deleus et al. (32). For each Tn-Seq dataset, a lognormal − negative binomial distribution was conservatively fit using genes with a median number of TA sites and the top 75% of reads per gene (nonessential genes) to identify parameters (μ, σ). Then, a theoretical distribution (f(σ)) was constructed using these two parameters for each gene size category based on the number of TA sites per gene (N TA). Background distributions for these categories were obtained from numerical sampling of the theoretical distribution. The actual number of reads for each gene was compared with the background distribution for the corresponding N TA category, and a P value was calculated as the probability of obtaining the number of reads (r) or less by chance. Two-layer multiple comparison adjustments were conducted. First, to obtain a mainly stringent essential set, we adjusted for the FWER using the Holm-Bonferroni method. Second, to reduce the risk of losing targets, we relaxed the stringency slightly to obtain a highly stringent essential set, by adjusting for the FDR using the Benjamin-Hochberg method. After either correction process, genes with an adjusted P value smaller than 0.05 in both replicates were identified as essential. A full description and calculations are provided in SI Appendix.

Method Validation with Clean Gene Deletions. Gene deletions were performed as previously described in strain PA14 (64). Gene deletions were confirmed by PCR amplification and sequencing. Successful gene deletion strains were grown in duplicate in LB medium at 37 °C for 16 h before diluting 10^7 in PBS. Five microliters of diluted culture was spotted to the five solid media used in this study and grown at 37 °C for 24 h. Images were captured, densitometry was performed using ImageJ (NIH), and growth was categorized relative to 10 wild-type replicates: essential (0–20%), growth-defective (21–50%), and nonessential (>50%).

In Vivo Mouse Models. All vertebrate animal experiments were done with the approval of the Massachusetts General Hospital’s Institutional Animal Care and Use Committee. Bacteria were grown to midlog, collected by centrifugation, washed, and resuspended in PBS. For the systemic infection model, 9-wk-old male BALB/c mice (The Jackson Laboratory) were infected i.p. with 4 mg of cyclophosphamide 3 d before infection. Mice were infected i.v. with 5 × 10^7 cfu per mouse. For the acute pneumonia model, mice were infected intranasally with 1 × 10^7 cfu per mouse. For both infection models, mice were euthanized 16 h postinfection and spleens (systemic) or lungs (pneumonia) were harvested and homogenized in 1 mL of PBS + 0.1% Triton X-100 using a TissueLyser LT (Qiagen) before plating to LB agar + 5 μg/mL irgasan to enumerate the bacterial burden.
