The medaka dhc2 mutant reveals conserved and distinct mechanisms of Hedgehog signaling in teleosts

Abstract

Background: Primary cilia are essential for Hedgehog (Hh) signal transduction in vertebrates. Although the core components of the Hh pathway are highly conserved, the dependency on cilia in Hh signaling is considered to be lower in fish than in mice, suggesting the presence of species-specific mechanisms for Hh signal transduction.

Results: To precisely understand the role of cilia in Hh signaling in fish and explore the evolution of Hh signaling, we have generated a maternal-zygotic medaka (Oryzias latipes) mutant that lacks cytoplasmic dynein heavy chain 2 (dhc2; MZdhc2), a component required for retrograde intraflagellar transport. We found that MZdhc2 exhibited the shortened cilia and partial defects in Hh signaling, although the Hh defects were milder than zebrafish mutants which completely lack cilia. This result suggests that Hh activity in fish depends on the length of cilium. However, the activity of Hh signaling in MZdhc2 appeared to be higher than that in mouse Dnchc2 mutants, suggesting a lower requirement for cilia in Hh signaling in fish. We confirmed that Ptch1 receptor is exclusively localized on the cilium in fish as in mammals. Subsequent analyses revealed that Fused, an essential mediator for Hh signaling in Drosophila and fish but not in mammals, augments the activity of Hh signaling in fish as a transcriptional target of Hh signaling.

Conclusions: Ciliary requirement for Hh signaling in fish is lower than that in mammals, possibly due to fused-mediated positive feedback in Hh signaling. The finding of this fish-specific augmentation provides a novel insight into the evolution of Hh signaling.

Keywords: Hedgehog signaling, Cilia, Medaka fish, Fused, dhc2, Cytoplasmic dynein heavy chain 2, Neural tube

Background

Hedgehog (Hh) signaling is an evolutionarily conserved signal transduction pathway which is essential for various aspects of embryogenesis including patterning events of the vertebrate neural tube and limb [1,2]. The mechanism of Hh-signal transduction has been the target of intense studies but remains only partially understood. One of the striking features of Hh signaling is that the primary cilium, a microtubule-based, immotile cell protrusion, is essential for Hh signaling in vertebrates but not in Drosophila [3]. A requirement for the cilium in this pathway was first identified by genetic screening in mice for ciliary mutants exhibiting phenotypes similar to those of Hh-pathway mutants [4]. However, subsequent genetic and molecular analyses demonstrated that cilium-dependency and the mediators of Hh signaling varies between fish and mammals, raising a question about conservation and evolution of the mechanism of Hh-signal transduction [5].

The formation and maintenance of cilia depend on the conserved process of intraflagellar transport (IFT) [6]. Ciliary proteins are transported along the ciliary axoneme by IFT machinery, driven by kinesin-based anterograde and dynein-powered retrograde transport. In the absence of Ift88, a component of anterograde IFT machinery, both mouse and zebrafish embryos lack all cilia and exhibit a severe reduction in Hh signaling. However, the phenotype is milder in zebrafish. In the neural tube, most of the Hh target genes are not expressed in mouse mutants, while the expression of low-threshold genes

remains and expands in zebrafish [4,5], suggested that cilium is required for Hh signaling also in fish, but the dependency on cilia is lower than that in mammals. However, it was still unclear how much Hh signaling in fish depends on cilia and what is the underlying mechanism for that difference.

Furthermore, Fused (Fu), a putative serine-threonine kinase, first identified as an essential mediator of Hh signaling in Drosophila, turned out to be dispensable for mammals, but it is indispensable for zebrafish [7-10]. These facts suggest that the pathway in zebrafish is more similar to that in Drosophila or placed in between Drosophila and mammals, making fish a unique model with which to investigate the transition state from ancestral to modern type of Hh signaling.

To further address this, we have generated a maternal-zygotic medaka mutant that lacks cytoplasmic dynein heavy chain 2 (dhc2; MZdhc2), an essential component of retrograde IFT, and compared the neural phenotypes of medaka and mouse mutants (Dnche2). We confirmed that the requirement for cilia in Hh signaling is lower in fish and revealed that the Hh activity in fish depends on the length of cilium. Additionally, Ptch1 receptor is localized to cilia in fish as in mammals. Subsequent analyses revealed that the difference in the requirement for cilia in Hh signaling across vertebrates can be interpreted by differential regulation and function of Fu.

**Results**

**Generation of maternal-zygotic aA90/dhc2 mutants**

The medaka aA90 mutant, isolated in an ENU-induced mutagenesis screening [11], is a recessive lethal mutant showing defects in left-right (L/R) axis determination (Figure 1A-B). L/R asymmetry is established by directional flow of extra-embryonic fluid surrounding the node (Kupffer’s vesicle in fish) by cilia. To identify the defective gene in aA90 mutant, we carried out positional cloning and narrowed down the aA90 locus to a 250 kb region in linkage group 13, which harbors a single predicted open reading frame, cytoplasmic dynein heavy chain 2 (dhc2), an IFT retrograde component (Additional file 1: Figure S1A). We found that aA90 has a 37.7 kb deletion in the dhc2 locus including the start codon, the heavy chain (HC)-HC, the HC-Intermediate chain interaction domain, and the AAA ATPase domain (Additional file 1: Figure S1A, C). Database searches demonstrated that the dhc2 gene exists as a single copy within the medaka genome. Due to long and complicated structure of the dhc2 gene (expands over 176 kb with 98 exons), we were unable to perform a rescue experiment by RNA injection. Injection of antisense morpholinos (MO) against the dhc2 gene into wild-type embryos significantly phenocopied aA90, which led us to conclude that dhc2 is the gene deficient in the aA90 mutant (Table 1).

Probably due to the maternal contribution of dhc2-gene products, the phenotype of aA90/dhc2 mutants was mild. For example, only one-fourth of the aA90/dhc2 homozygous mutants showed situs inversus (Table 1). To completely eliminate dhc2 products, we have generated maternal-zygotic aA90/dhc2 mutants using the germline-replacement technique [12,13] with some modifications (Figure 2). Crosses of females with mutant germ cells and heterozygous males (dhc2+/+) generated 50% homozygous mutants that lacked both maternal and zygotic products of dhc2 (MZdhc2) and 50% heterozygous mutant embryos that lacked only the maternal dhc2 contribution (Mdhc2).

As expected, the complete loss of dhc2 activity increased the frequency of situs inversus to 52.8% (Table 1, Figure 1A-D) as well as enlarged ventricles and expanded nephric duct (Figure 1E-H, M-P). Moreover, the typical phenotypes of defective Hh-signaling, severe ventral curvature and U-shaped somites instead of chevron-shaped ones, were observed in MZdhc2 mutants, but not in zygotic (Zdhc2) or Mdhc2 mutants (Figure 1I-L, Q-T), indicating reduced levels of Hh signaling. Importantly, the morphology of cilia was dramatically shortened as demonstrated by scanning electron microscopy (SEM) (Figure 3A). To expose the ventricular surface area of neural tubes, we exteriorized this area with cilia, prior to fixation (Figure 3B) and found that cilia on the surface of non-floor plate (FP) neuroepithelial cells (LNT, lateral neural tube) and longer ones on the FP cells (VM, ventral midline) were much shorter and bloated in MZdhc2 than their wild-type counter parts (Figure 3A). In the Kupffer’s vesicle and somites, cilia were shortened in MZdhc2, as compared with those in WT, Mdhc2 and Zdhc2. The ciliary morphology in Zdhc2 mutants appeared normal at least until the segmentation stages, but subtle defects in function or lately overt defects could account for their milder phenotypes (Table 1, Additional file 2: Figure S2, data not shown). The ciliary phenotypes in MZdhc2 mutants are nearly identical to those in mouse Dnche2 +/- [14,15], and thus the analysis of the Hh activity in MZdhc2 mutants enabled us to examine differences and distinct mechanisms between fish and mouse in the requirement for cilia in Hh signaling.

**Patterning of the spinal cord in MZdhc2 mutants**

In the neural tube, sonic hedgehog (Shh) ligand forms a dorso-ventral (DV) gradient with the highest concentration ventrally, and specifies cell fates in a concentration-dependent manner [16]. Thus, the expression of cell-type specific genes serves as a readout of Hh activity and delineates domains in the ventral neural tube. Roughly, from ventral to dorsal, gene expression is as follows: foxa2 in the FP, nkd2.2 in p3 neuron precursors, olig2 in motor neuron precursors (pMN), nkx6.1/6.2 in p3/pMN/p2
progenitors, and pax6, pax3, dbx1 and dbx2 in dorsally located neuron precursors and their expressions are mutually exclusive underlined by their repressive interactions (Figure 3D) [17,18]. Shh is known to induce the expression of the ventral genes (foxa2, nkh2.2, olig2, nkh6.1 and nkh6.2), while suppressing the dorsal genes (pax6, pax3, dbx1 and dbx2) [17-19]. We first confirmed that shh was normally expressed in the medial FP (MFP) and underlying notochord of MZdhc2 mutants (Figure 3C, Additional file 3: Figure S3J), suggesting that defects observed in mutants are mainly ascribed to signal transduction defects.

In MZdhc2 mutants, foxa2 and nkx2.2 were expressed (Figure 3C, Additional file 3: Figure S3H-I), whereas ventral intermediate genes, olig2, nkh6.1 and nkh6.2 were dorsally expanded and this dorsal expansion was not observed in Zdhc2 (Figure 3C, Additional file 3: Figure S3E-G). Dorsal expansion of olig2 expression in MZdhc2 was also observed at three different axis levels (Additional file 4: Figure S4). The expression of these ventral genes suggests that the Hh pathway is activated in cells with severely shortened cilia and even reaches the high levels of activation on the most ventral side. Like zebrafish, foxa2 expression in the medial FP is Hh-independent in medaka embryos (Additional file 5: Figure S5B), and thus we will use nkx2.2 expression as a marker of the high level of Hh activation. Also, it is worth noting that the most ventral region appeared to be missing in MZdhc2 embryos, as the expression domains of nkx2.2, separated by the negative medial FP cells, frequently merged in the medial region (Figure 3C). However, due to the lack of a specific marker for this region, we were unable to determine a cell type specifically defective in MZdhc2 embryos.

The expansion of lower-threshold gene expression (olig2, nkh6.1 and nkh6.2) also suggests that the area of low Hh activation abnormally expanded dorsally in the mutant neural tube. This was further supported by

dorsally retracted expression of \textit{pax6}, \textit{pax3}, \textit{dbx1} and \textit{dbx2}, observed in MZ \textit{dhc2} mutants (Figure 3C, Additional file 3: Figure S3A-D). In \textit{Dnchc2}-mutant mice, \textit{nkx2.2} expression was reported to be lost, but \textit{olig2} was expanded [14,15]. Thus, there are similarities and differences in the neural tube phenotypes between fish and mouse \textit{dhc2} mutants (Figure 4), both of which we addressed in the following experiments.

**Lower Hh pathway activation in mutant cells**

To examine the activation level of Hh pathway in mutant cells, we treated MZ \textit{dhc2} embryos with various concentrations of cyclopamine, a potent antagonist of Smoothened (Smo). Intriguingly, in the MZ \textit{dhc2} group, the percentage of \textit{nkx2.2}-positive embryos started to decrease at a cyclopamine concentration as low as 0.25 μM, and went down below 50% at 0.5 to 1 μM, while at such low concentrations, 100% of embryos maintained \textit{nkx2.2} expression in the wild-type and M \textit{dhc2} groups (Figures 5A-B, Additional file 6: Table S3). These results suggest that the activity of Hh signaling in mutant cells is compromised at the level or upstream of Smo, but still high enough to express the ventral-most marker, \textit{nkx2.2}.

**Patched1 localizes to cilia in medaka fish**

In murine cells, Ptch1 receptor was reported to localize the primary cilium at least cultured cells and paraxial mesoderm cells [20,21], whereas it is not the case in \textit{Drosophila} which does not require cilia for the reception of Hh [3]. However, Ptch1 localization was unknown in fish. To address this, we generated an antibody against medaka Ptch1 (Additional file 7: Figure S6A-B, Additional file 8: Table S2), and examined the distribution of Ptch1 in wild-type and MZ \textit{dhc2} neural-tube cells. Firstly, we confirmed that Ptch1 expression in medaka is diminished by cyclopamine treatment (data not shown) and in the morphants, the number of Engrailed-expressing cells in somites was increased (Additional file 7: Figure S6D), similar to zebrafish morphant [10].

As shown in Figure 5C, Ptch1 was localized to the cilia of neuroepithelial cells which are exteriorized with forceps before fixation (Figure 3B) in WT. Importantly, Ptch1 was still localized to severely shortened cilia in MZ \textit{dhc2} (Figure 5C). The specificity of the antibody was confirmed by knockdown and overexpression experiments (Additional file 7: Figures S6C, E). These results indicate that the cilium is the site for Hh receptor Ptch1 localization in medaka.

**MZ\textit{dhc2} cells are less sensitive to Shh**

Although the activation level of Hh signaling is still sufficient to induce all target genes in mutant cells, the amount of Ptch1 in severely shortened cilia is likely to be decreased. This could explain the higher sensitivity to cyclopamine in the above experiment (Figure 5A-B). In other words, MZ \textit{dhc2} cells could be less sensitive to Shh.
Shh. To test this idea, we transplanted wild-type cells into MZdhc2 blastula or Mdhc2 (control), and examined olig2 expression when donor cells were localized in host neural tubes (Figure 5D). We determined the genotype of MZdhc2 and Mdhc2 by the eye phenotype at 16-somite stage when transplanted embryos were fixed for the analysis (Additional file 9: Figure S7). Remarkably, olig2-positive WT cells were frequently found in the region more dorsal to the host olig2-expression domain in MZdhc2 embryos (Figure 5D, WT to MZdhc2, arrowhead; n = 9/10), while no such ectopic expression was detected in control transplants (Figure 5D, WT to Mdhc2, arrowhead; n = 15/15). These results demonstrate that Hh-activation of MZdhc2 cells is lower than
that in WT cells, even if they are exposed to the same concentration of Hh-ligand.

**Fused forms a positive-feedback loop in fish**

The presence of nkd2.2 expression is unique in MZdhc2 as mouse Dnchc2 mutants lose nkd2.2 expression [14,15]. The same tendency was observed in ift88 mutants that completely lack cilia; only zebrafish mutants maintain the expression of intermediate genes like olig2 [4,5], implying that the activation of Hh signal is enhanced in fish. To explore a teleost-specific mechanism, we focused on fused (fu), an intracellular mediator of Hh signaling downstream of Smo in Drosophila, which has evolved divergent roles in the vertebrate lineage: one for Hh signaling and the other for ciliary motility. Interestingly, murine Fu is dispensable for Hh signaling and specifically participates in the motility of cilia, whereas it is required for both in zebrafish [7,10]. We first tested if fu is essential for Hh signaling in medaka by injecting fu MO (600 μM) targeted to the splicing site (Additional file 10: Figure S8A) and observed the loss of nkd2.2 expression (Figure 6A; n = 14/15). Additionally, morphants injected together with fu mRNA rescued nkd2.2 expression (Additional file 10: Figure S8B; n = 14/14) and
injection of fu mRNA into WT embryos elevated Hh activity as indicated by the expansion of the ventral intermediate genes, olig2 and nkx6.1 (Figure 6E, Additional file 10: Figure S8C; n = 9/14, 9/9, respectively). We then knocked down fu in MZdhc2 mutants to see if the remaining expression of Hh target genes in those mutants also depends on Fu. However, under our experimental conditions, most of the MZdhc2 mutants injected with fu MO (600 μM) died probably due to a requirement of Fu in earlier development [22], and we therefore reduced the concentration of fu MO (300 μM), when injected into MZdhc2 mutants. These injected MZdhc2 embryos failed to express nkx2.2 (Figure 6B). Interestingly, the expansion of the ventral intermediate gene, olig2, was also rescued (Figure 6B). These results demonstrate that fu is indispensable for Hh signaling in wild-type and mutant medaka embryos and its overexpression augments the signal.

fu is known to be expressed ubiquitously in zebrafish at early developmental stages [22], but the precise pattern and regulation of fu expression during neural tube patterning have not been reported. Our further analysis revealed that fu expression is restricted to the ventral part of neural tube where high to low levels of Hh signaling are activated at 16-somite stage in medaka (Figure 6C). Furthermore, fu expression was dorsally...
expanded in MZdhc2 neural tubes (Figure 6C), like the ventral intermediate genes. These results suggest that fu is a transcriptional target of Hh signaling. To test this possibility, we treated wild-type embryos with 5 μM cyclopamine and observed severe reduction or loss of fu expression in cyclopamine-treated embryos (Figure 6D), indicating that fu expression is induced by Hh signaling downstream of Smo. We also confirmed that fu expression in zebrafish is ventrally restricted in the neural tube and depends on Hh signaling (Additional file 10: Figure S8D).

We finally asked if Fu, when overexpressed, can restore Hh signaling, when Smo-mediated signaling is compromised. For this, embryos were treated with 2.5 μM cyclopamine (intermediate dose, Figure 5A) together with fu mRNA injection. Those injected embryos showed weak but significant up-regulation of nkx2.2 (n = 12/18) as compared with cyclopamine-treated control embryos (n = 1/14) (Figure 6F), suggesting that Fu augments Hh activity downstream of Smo. Given that Fu is a positive mediator of Hh signal transduction, Fu is likely to form a positive feedback loop downstream of Smo to reinforce Hh signal in teleost target cells (Figure 7).

**Discussion**

In the present study, utilizing the medaka mutant with severely shortened cilia, MZdhc2, we demonstrated that shorter cilia mediate less Hh activation in fish. This result suggests that they mediate Hh signaling in a length-dependent manner. We also found that Ptch1 receptor is exclusively localized on the cilium in fish. These are largely consistent with the observation of murine ciliary mutants. Furthermore, the present study has addressed why the expression of low-threshold target genes is expanded in mutant neural tubes and how Hh signal is augmented in fish mutant cells.

A possible role for cilia in Hh gradient formation

Olig2-positive wild-type cells in mutant neural tubes were positioned more dorsally than dorsal boundary of olig2 expression in wild-type neural tubes (Figure 5D). This result, though indirectly, suggest that the gradient profile of Hh ligand dorsally shifts in mutant neural tubes.

Dorsal expansion of Shh ligand was directly observed with smoothened mouse mutants [23] and this can be interpreted as a consequence of the reduced amount of Ptc1 receptor, a downstream target of Hh signaling. Indeed it has been proposed that the Shh gradient is regulated by a Shh-induced negative-feedback mechanism in which ligand binding to Ptc1 at the cilia sequesters Hh ligand itself in the intercellular space [18]. It is thus conceivable that in ciliary mutant neural tubes, the reduced amount of Ptc1 on cilia caused a dorsally shifted Hh gradient, and thereby the expression domain of ventral low-threshold target genes is expanded, although further confirmation by direct imaging is required. Consistently, the neural tube in Dnchc2 mutants also exhibits the expansion of low threshold gene expression [14,15]. Thus in vertebrates, the length of cilia could be one of the factors that affect the Hh gradient in the neural tube. Of course, we still cannot rule out the possibility that wild-type cells, when placed in mutant background, become more sensitive than those in a control background.

**Teleost-specific augmentation of Hh pathway mediated by fused**

In the present study, we propose that Fu is a key to account for the difference in activation level between mammals and fish in ciliary mutants. Fused is a crucial mediator of Hh signaling in Drosophila and zebrafish, but not in mammals [7]. We first confirmed that fu was required for Hh signaling in medaka like zebrafish, and

![Figure 7 Proposed model of the distinct features of Hh signal transduction in insect, fish and mammal.](image)
next found that the expression of fu in neural tube is restricted to the ventral part and induced by Hh signaling in fish. Subsequent analyses demonstrated that Fu forms a positive-feedback loop downstream of Smo (Figure 7); Fu activates the Hh pathway which then leads to the up-regulation of Fu. The positive feedback centered by Fu could augment Hh signal in ciliary mutant cells with lower input of Smo-mediated signaling. This could thus explain why the phenotype of fish ciliary mutants are milder than that of mammalian counterparts. Of course, Fu may not be a mere component that differentiates the ciliary dependency in the two vertebrate models. Indeed, in zebrafish, low levels of Hh activation mediated by Gli1 are known to occur in a Hh-independent manner and its mechanism remain elusive [5].

What is the biological and evolutionarily significance of the positive-feedback mechanism in Hh signaling. A hint could be found in the speed and mode of neurulation in fish. According to the recent report by Xiong et al. [24], specification of neural cell types in zebrafish begins earlier and proceeds faster under the noisy conditions of cell movements in the formation of the neural keel. Whereas in other vertebrates, such as chick and mice, neurulation proceeds gradually and steadily in an epithelialized cell sheet, following an established Shh gradient. A rapid and amplified response to Shh in target cells would thus be necessary in fish neurulation. Xiong et al. also showed that specified neural progenitors sort to form sharply bordered domains from mixed progenitor populations. However, this apparently contradicts our transplantation result showing ectopic expression of a specific marker in wild-type donors (Figure 5D), suggesting that multiple strategies, including sorting and position-dependent determination, are employed to achieve a robust pattern. Recently, the presence of cilium-mediated signaling was reported in the olfactory epithelium of Drosophila [24], suggesting the evolutionarily ancient origin of this mechanism. Thus, further analysis of Hh signaling in diverse species and tissues will provide greater insight into the evolution of this crucial signaling pathway.

Conclusion
The present study strengthens the idea of a conserved role of primary cilium in Hh-signal transduction in vertebrates, but also uncovered a teleost-specific augmentation mechanism mediated by Fu. The fish-specific augmentation can serve as the mechanism that accounts for the lower cilia-dependency for Hh signaling in fish and gives novel insight into the evolution of Hh signaling.

Methods
Fish strains
All studies of medaka (Oryzias latipes) were carried out using d-rR strain of a closed colony. And zebrafish (Danio rerio) were Riken wild-type (RW). All experimental procedures and animal care were carried out according to the animal ethics committee of the University of Tokyo.

Whole mount in situ hybridization
In situ hybridization analyses were performed as previously described [25]. The cDNAs used as the templates for the probes were described in Additional file 11: Table S1.

Histology
For histological analysis, fixed embryos were embedded in Technovit 7100 ( Heraeus Kulzer). Scanning electron-microscope observations were performed as previously described [26].

Immunofluorescence
Whole-mount immunostaining was performed as described previously [27]. The antibodies used were as follows: Polyclonal anti-medaka Pch1 [amino acids 169–405; Additional file 7: Figure S6B] antibody were raised by immunization of rabbits with bacterial-expressed His-tagged truncated proteins and the antibody was affinity-purified as described [28]; acetylated α-tubulin (Sigma); γ-tubulin (Sigma).

Chemical treatment
For cycloamine (Enzo Life Sciences) treatment, dechorionated embryos were incubated from 30-50% epiboly stage onward.

(E) PtcH1-Myc (magenta) was specifically localized to cilia in neural tube and the signals are well merged with anti-PtcH1 antibody signals (green) in a cross-sectional view at 16-somite stage.

**Additional file 8: Table S2.** Accession numbers used to create the phylogenetic trees depicted in Additional file 7: Figure S6A.

**Additional file 9: Figure S7.** Optic cup and lens formation were significantly defected in MZdhc2, as compared with WT, Zdhhc2 and Mdhc2. Dorsal views of the eye in WT, Zdhhc2, Mdhc2 and MZdhc2 at 16-somite stage. Arrows indicate optic cup and arrow heads indicate lens. Scale bar: 100 μm.

**Additional file 10: Figure S8.** fu knockdown, overexpression in medaka, and fu expression pattern in Zebrafish. (A) Knockdown of fu was performed using the morpholino-oligonucleotide (MO) for splice blocking (S′-CAACACATCTTGTGGACCAAAAA-A-3′). Diagram of altered fu splicing in mutants of fu-tle2 inserts intron 1 (+in1, 1′), resulting in an out-of-frame truncation of the fu protein, and splices exon 2 to a cryptic acceptor in exon 3 (–Ex. 2), causing an out-frame mutation of fu. The effect of the splice-blocking MO was verified by RT-PCR from 20 embryos total RNA (16-somite stage). Primers for checking the effect of MO were indicated in A (arrows). MO caused splice-blocking effectively. (B) fu mRNA injection rescued nkx2.2 expression in fu morpholino injected embryos. (C) fu overexpression induced ectopic nkx1.1 and olig2 expression. (D) fu expressed in Hedgehog-dependent fashion also in zebrafish. The embryos treated with cyclopamine did not express fused or nkx2.2a. Scale bar: 500 μm in lateral view in B, C, D; 20 μm in cross-section in D.

**Additional file 11: Table S1.** Primers used in this study.

**Abbreviations**
dhc2: cytoplasmic dynamin heavy chain 2; dplf: Days post-fertilization; ENU: N-ethyl-N-nitrosourea; fu: fused; GFP: Green fluorescent protein; Hc: Heavy chain; Hh: Hedgehog; IC: Intermediate chain; IFT: Intraflagellar transport; Kv: Kupffer’s vesicle; LNT: Lateral neural tube; Mdhc2: Maternal mutant of dhc2; MO: Morpholino antisense oligonucleotide; MZdhc2: Maternal-zygotic mutant of dhc2; ORF: Open reading frame; PtcH1: Patched 1; Shh: Sonic hedgegog; Smo: Smoothened; VM: Ventral midline; WT: Wild type; Zdhc2: Zygotic mutant of dhc2.

**Competing interests**

The authors declare that they have no competing interests.

**Authors’ contributions**

All experiments were planned by TY, TT, MT and HT, and conducted by TY, TI and HH. The manuscript was prepared by TY and HT. All authors read and approved the final manuscript.

**Acknowledgements**

We thank Dr. K. Kamura, Mr. Y. Masuda, Dr. S. Koshida, and Dr. A. Shimada for their help in starting this work, Dr. A. Terashima for critical reading of the manuscript and Ms. Y. Ozawa for fish care. This work was supported in part by Grants-in-Aid for Scientific Research on Innovative Areas 2047030 to H.T.
