Abstract

Background: Adenine nucleotide/phosphate carriers (APCs) from mammals and yeast are commonly known to adapt the mitochondrial adenine nucleotide pool in accordance to cellular demands. They catalyze adenine nucleotide - particularly ATP-Mg - and phosphate exchange and their activity is regulated by calcium. Our current knowledge about corresponding proteins from plants is comparably limited. Recently, the three putative APCs from Arabidopsis thaliana were shown to restore the specific growth phenotype of APC yeast loss-of-function mutants and to interact with calcium via their N-terminal EF-hand motifs in vitro. In this study, we performed biochemical characterization of all three APC isoforms from A. thaliana to gain further insights into their functional properties.

Results: Recombinant plant APCs were functionally reconstituted into liposomes and their biochemical characteristics were determined by transport measurements using radiolabeled substrates. All three plant APCs were capable of ATP, ADP and phosphate exchange, however, high preference for ATP-Mg, as shown for orthologous carriers, was not detectable. By contrast, the obtained data suggest that in the liposomal system the plant APCs rather favor ATP-Ca as substrate. Moreover, investigation of a representative mutant APC protein revealed that the observed calcium effects on ATP transport did not primarily/essentially involve Ca\(^{2+}\)-binding to the EF-hand motifs in the N-terminal domain of the carrier.

Conclusion: Biochemical characteristics suggest that plant APCs can mediate net transport of adenine nucleotides and hence, like their pendants from animals and yeast, might be involved in the alteration of the mitochondrial adenine nucleotide pool. Although, ATP-Ca was identified as an apparent import substrate of plant APCs in vitro it is arguable whether ATP-Ca formation and thus the corresponding transport can take place in vivo.

Background

The mitochondrial carrier family (MCF) comprises structurally related but functionally diverse proteins that are characteristic for and generally restricted to eukaryotes [1–5]. MCF proteins represent the main solute carriers in the inner mitochondrial membrane and catalyze the translocation of various metabolites, such as nucleotides, cofactors, carboxylates, amino acids etc (for review see [6]).

Mitochondrial ATP-Mg/phosphate carriers (APCs) represent a specific MCF subgroup comprising carriers from different eukaryotes that are phylogenetically related to the well characterized ADP/ATP carriers (AACs) required for mitochondrial energy passage (for review see [6, 7]). Over the past years the physiological and biochemical properties of the single yeast APC isoform Sal1p (suppressor of Δaac2 lethality) as well as of various mammalian homologs became more and more clarified [8]. Initially, Sal1p was shown to suppress the growth phenotype of yeast impaired in mitochondrial energy transport (due to AAC deletion or inhibition). In a similar fashion, AAC compensates the loss of functional Sal1p
[8]. Subsequent studies revealed that Sal1p and its mammalian homologs mediate the counter exchange of adenine nucleotides and phosphate [9–13]. Therefore, the redundant physiological function of Sal1p and AAC supposedly was not primarily energy exchange but adenine nucleotide translocation, most likely ATP entry into mitochondria [13, 14].

Alteration of the mitochondrial adenine nucleotide pool by adenine nucleotide exchange with phosphate was shown to affect different physiological processes, such as glucose metabolism, oxidative phosphorylation, mitochondrial biogenesis and DNA maintenance in yeast or mammals [9–13]. APC proteins apparently prefer two-fold negatively charged substrates, either ATP in complex with Mg\(^{2+}\) (ATP-Mg\(^{2+}\)), protonated ADP (HADP\(^{2+}\)) or HPO\(_4^{2-}\), which makes the catalyzed transport electroneutral [15]. The composition (respective concentrations) of the different substrates at the matrix and cytosolic sides of the carrier determine whether adenine nucleotides preferentially become exported or imported [11, 15].

Interestingly, addition of Ca\(^{2+}\) to isolated mitochondria as well as metabolic situations that result in increase of free cytosolic Ca\(^{2+}\) were shown to enhance mitochondrial adenine nucleotide levels by stimulation of APC activity in mammals and yeast [8, 16–18] (for review see [19]). In one aspect APC proteins considerably differ structurally from typical MCF proteins; they are N-terminally extended by a domain that is exposed to the inter-membrane space of the mitochondrion and contains up to four putative Ca\(^{2+}\)-binding EF-hand motifs [20–22]. Very recent structural studies with the N-terminal domain of human APC isoform 1 (also termed SCaMC1 for short Ca\(^{2+}\)-bound state is quite compact and rigid whereas the apo (Ca\(^{2+}\)-free) state appeared more flexible [21, 22]. Moreover, interaction studies with the two individual SCaMC1 domains, the Ca\(^{2+}\)-binding part and the C-terminal transmembrane region, led to the assumption that the apo state of the N-terminal domain forms a cap that closes the translocation pathway whereas Ca\(^{2+}\)-binding causes cap removal/opening and thus transporter activation [21, 22].

In contrast to yeast and mammals [8, 12, 16, 18, 23–25] analyses concerning the net adenine nucleotide transport of mitochondria in plants are still rudimentary. Previous studies led to controversial results but have indicated that plant mitochondria are capable of net adenine nucleotide uptake [26–31]. Arabidopsis thaliana possesses three putative APC proteins (AtAPC1-3) that exhibit high amino acid sequence similarities to their human and yeast counterparts. Phylogenetic analysis of MCF proteins shows that APCs cluster together and that plant APCs form a sister group to the human and yeast orthologs [6]. Similar to yeast or mammalian APCs, the plant pendants contain an N-terminal extension with four putative EF-hand motifs and were recently shown to interact with Ca\(^{2+}\) at least in vitro [32]. Moreover, all three plant isoforms were able to rescue the specific growth phenotype of Δsal1p yeast mutants [32]. Therefore, AtAPC1-3 isoforms were suggested to represent Ca\(^{2+}\)-regulated ATP-Mg/phosphate transporters. To gain first insights into the biochemical characteristics of the three APCs from A. thaliana we reconstituted the heterologously expressed proteins into liposomes and investigated their capacity for adenine nucleotide transport. Our data indicate that plant APCs mediate antiport of ATP, ADP and phosphate and therefore might be involved the alteration of the mitochondrial adenine nucleotide pool. Moreover, the determined transport characteristics suggest that in the in vitro system, the plant APCs preferentially import the Ca\(^{2+}\)- and not the Mg\(^{2+}\)-complexed form of ATP.

**Methods**

**Generation of expression constructs**

The coding sequences of AtAPC1-3 were amplified from Arabidopsis cDNA with specific primers via Pfu polymerase-mediated PCR. For generation of the truncated AtAPC2 mutant protein lacking its Ca\(^{2+}\)-interacting N-terminus a sense primer was chosen that internally hybridizes with the corresponding full-length sequence resulting in a recombinant protein starting at amino acid position 164 directly after the fourth predicted EF-hand motif coding region. The isopropyl β-D-thiogalactopyranoside (IPTG)-inducible T7 RNA polymerase pET-vector/Rosetta™ 2 expression system (Merck Biosciences, Novagen®, Darmstadt, Germany) was used for heterologous protein synthesis. Accordingly, the primers were adapted to allow insertion into the expression vector pET16b in frame with the histidine-tag coding sequence. The coding sequence of AtAPC1 was inserted via Ndel (sense primer) and Xhol (antisense primer) whereas the remaining sequences were inserted via Xhol (sense primer) and BamH1 (antisense primer). Correctness of the respective expression constructs was verified by sequencing.

**Heterologous protein synthesis and detection**

For heterologous protein synthesis Rosetta™ 2 cells were transformed with the expression constructs and cultured in 50 mL standard Terrific Broth (TB) medium at 37 °C under vigorous shaking. At an OD\(_{600}\) of 0.5, expression was induced by addition of 1 mM IPTG. Two hours after induction, cells were concentrated by centrifugation (3000 g, 5 min, 4 °C) and rapidly frozen (in liquid nitrogen). The frozen cell pellet was resuspended in buffer R (25 % sucrose, 50 mM Tris, pH 7.0, 1.5 % Triton X-100, 18.75 mM EDTA) supplemented with 1 mM PMSF, a pinch of DNAse and RNAse and incubated for...
approximately 30 min at 37 °C to stimulate autolysis by the endogenous lysozyme which was released from the cells due to the freeze/thaw procedure. Subsequent sonication additionally supported cell disruption. Inclusion bodies were separated from soluble and membrane proteins of the cell homogenate by centrifugation (20,000 g, 15 min, 4 °C).

For documentation of heterologous protein synthesis, an aliquot of the inclusion bodies fraction was used for SDS-PAGE, Western-blotting and immune detection. For this, inclusion bodies were resuspended in buffer R and an appropriate volume of 6 x concentrated sample buffer medium (375 mM Tris/HCl, pH 6.8, 0.3 % SDS, 60 % glycerol, 1.5 % bromophenol blue) was added. Protein separation was performed in a discontinuous, denaturing system with a 3 % stacking and a 12 % separating polyacrylamide gel [33]. Following electrophoresis, the gel was coomassie stained or used for Western-blotting. Immune detection was performed using a monoclonal anti poly His IgG (Sigma; http://www.sigmaaldrich.com) combined with a secondary alkaline phosphatase conjugated anti-mouse IgG (Sigma). Alkaline phosphatase activity was detected by staining with nitro blue tetrazolium chloride/5-bromo-4-chloro-3-indolyl phosphate toluidine salt.

Purification of inclusion bodies

Basically, purification of inclusion bodies as well as their solubilization, refolding and integration into lipid/detergent micelles was performed according to [34]. For this, the cell pellet of the inclusion body fraction washed in buffer W1 (20 ml 1 M urea, 1 % Triton X-100 and 0.1 % β-mercapto-ethanol). After centrifugation (20,000 g, 15 min, 4 °C) inclusion bodies were additionally washed in buffer W2 (20 mM Tris, pH 7.0, 0.5 % Triton X-100, 1 mM EDTA, 0.1 % β-mercapto-ethanol) and finally in buffer W3 (50 mM Tris, pH 7.0, 1 mM EDTA, 0.1 % β-mercapto-ethanol). Solubilization of the purified inclusion body proteins was achieved by resuspension in buffer medium S (10 mM Tris, pH 7.0, 0.1 mM EDTA, 1 mM DTT, 0.05 % polyethylene glycol 4000) containing 1.67 % of the detergent n-lauroylsarcosine and incubation for 15 min on ice. The protein fraction was diluted (threefold) with 10 mM Tris (pH 7.0) and finally, the solubilized proteins were separated from insoluble aggregates by centrifugation (12,000 g, 4 min, 4 °C).

Preparation of proteoliposomes and transport measurements

For preparation of proteoliposomes 100 μg of the solubilized proteins were mixed with 20 mM Hepes, pH 7.0 and 1 mM PMSF. To obtain vesicles with internal counter exchange substrates 5 mM of phosphate or adenosine nucleotides were added to the protein mixture. Preparation of mixed detergent-lipid micelles (100 mM PIPES, pH 7.0, 20 mg phosphatidylcholine, 1.6 mg cardiolipin, 28 mg C16:E5) and detergent removal by amberlite XAD-2 beads was performed exactly as given by Heimpel et al., [34]. Overnight incubation with bio-beads completed protein refolding and proteoliposome formation. External buffer medium and loading substrates were removed from the vesicles (500 μL) by desalting with NAP-5 columns (GE Healthcare; http://www.gehealthcare.com). Columns were equilibrated and liposomes were eluted with of import buffer (50 mM NaCl, 10 mM PIPES, pH 7.5). For transport measurements 50 μL of these proteoliposomes were mixed with 50 μL of import buffer supplemented with the indicated concentrations of [α32P]-ATP, [α32P]-ADP, [45Ca], MgCl2 and CaCl2 and incubated at 30 °C. At the given time points import was terminated by removal of external import medium via vacuum filtration as described in [35]. Briefly, liposomes were loaded to pre-wetted filters (mixed cellulose ester, 0.45-μm pore size; Whatman) and washed rapidly with phosphate buffer. Imported radioactivity was quantified by scintillation counting (Beckman LS6500; Beckman Coulter). For [45Ca] uptake measurements import was terminated and non-imported Ca2+ was removed by EGTA addition (2 mM) and incubation for 15 s prior to vacuum filtration and washing.

Results

Recombinant plant APCs act as ATP, ADP and P, antiporters

To determine functional properties of the different APCs from A. thaliana we used the heterologous Escherichia coli expression system for production of the respective isoforms and performed transport measurements after carrier reconstitution into artificial lipid vesicles, so called liposomes. This approach was previously successfully applied to biochemically characterize several MCF proteins, including two selected human SCaMC isoforms [12, 34, 36–38].

The three plant APCs were heterologously expressed as N-terminal His-tag fusions. Like previously observed for many MCF proteins [12, 34, 36–38] also plant APCs were synthesized at high levels and accumulated in form of insoluble inclusion bodies (Additional file 1: Figure S1A and B). The aggregated proteins were enriched, purified, solubilized and finally refolded during their integration into liposomes.

Import measurements were performed on proteoliposomes either harboring or lacking selected possible counter exchange substrates in the lumen (Fig. 1, Additional file 2: Figure S2). This allowed investigation of in vitro transport activities and hence functionality of the reconstituted proteins as well as of the catalyzed transport mode. All recombinant plant APCs mediated time dependent uptake of [α32P]-ATP into phosphate (Pi) loaded liposomes (Fig. 1a, c, e, black rhombs) and no comparable accumulation of
radioactivity was observable with corresponding vesicles lacking Pi in the lumen (Fig. 1a, c, e, open rhombs). This observation already demonstrates that plant APCs can act as antiporters; ATP/Pi exchange by the different APC isoforms was linear for at least 5 min. Maximal uptake via AtAPC1 of ~ 6 nmol/mg protein was reached after 10 to 15 min (Fig. 1a, black rhombs), whereas AtAPC2 and AtAPC3 show marginally or considerably higher transport rates that approached a maximum of ~ 9 nmol/mg protein and ≥ 17 nmol/mg protein after 20 min, respectively (Fig. 1c and e, black rhombs).

Yeast Sal1p and mammalian SCaMCs were shown to discriminate against free ATP as substrate or at least to prefer the Mg2+-complexed form of ATP over free ATP [12, 15, 16, 39]. To check whether this is also true for the plant APCs, the influence of Mg2+ on ATP transport was analyzed. To this end, the ATP transport medium was supplemented with 500 μM MgCl2 to convert ~ 80 % of free ATP (ATP4−) into the Mg2+-complexed form (ATP-Mg2−) ([40]). ATP-Mg2− and HPO42− exchange results in an electroneutral transport. In case of AtAPC1 and AtAPC3 addition of Mg2+ caused moderate (~1.6-fold to 2.0-fold) increase in adenine nucleotide/Pi exchange compared to ATP without Mg2+ (Table 1; Fig. 1a and e, compare gray circles and black rhombs) whereas transport by AtAPC2 was stimulated to a lesser extent (Table 1; Fig. 1c, compare gray circles and black rhombs).
Table 1 Comparison of counter exchange rates of AtAPC1-3

| Exchange (import/export) | AtAPC1 | AtAPC2 | AtAPC3 |
|--------------------------|--------|--------|--------|
| ATP/P<sub>i</sub>         | 4.1    | 5.0    | 7.2    |
| ATP-Mg/P<sub>i</sub>      | 6.4    | 6.7    | 13.5   |
| ATP/ATP                   | 17.4   | 7.7    | 20.1   |
| ATP-Mg/ATP                | 28.9   | 10.3   | 28.1   |
| ADP/P<sub>i</sub>         | 7.6    | 5.7    | 11.3   |
| ADP/ADP                   | 39.8   | 12.2   | 42.0   |

ATP and ADP transport was allowed for 10 min. Rates represent net values of transport (minus corresponding transport into non-loaded liposomes) and are given in nmol/mg protein. For investigation of Mg<sup>2+</sup>-impact on ATP uptake 500 μM of MgCl<sub>2</sub> were added to the transport medium. The complete time courses of ATP and ADP transport are displayed in Fig. 1 and in Additional file 2: Figure S2.

To unravel whether the stimulatory influence of Mg<sup>2+</sup> on ATP uptake is due to general preference for ATP-Mg as substrate or rather due to the electroneutrality of the corresponding transport process we investigated Mg<sup>2+</sup>-effects on ATP homo-exchange. Homo-exchange of ATP is electroneutral but becomes electrogenic when ATP-Mg<sup>2+</sup> is exchanged with ATP<sup>4+</sup>. Comparison of the transport rates indicates that AtAPC1, AtAPC3 markedly and AtAPC2 slightly prefer ATP homo-exchanges over the corresponding ATP/P<sub>i</sub> hetero-exchanges (Table 1; compare Fig. 1a, c, e with b, d, f, black rhombs). Moreover, ATP homo-exchanges of all three AtAPCs became further enhanced by Mg<sup>2+</sup> (Fig. 1b, d, f, compare gray circles and black rhombs) and the degree of Mg<sup>2+</sup>-dependent stimulation was nearly identical to that of the ATP/P<sub>i</sub> hetero-exchange (Table 1). The observed stimulatory effects of Mg<sup>2+</sup> on ATP/P<sub>i</sub> and ATP/ATP transport indicate that AtAPC1 and 3 generally prefer ATP-Mg as substrate whereas AtAPC2 apparently only slightly favors the Mg<sup>2+</sup>-complexed form.

Because ADP represents an additional substrate of yeast Sal1p and human SCaMCs [12, 15, 18, 39] we verified whether this nucleotide is also transported by the plant orthologs in our in vitro system. For this, uptake of radiolabeled ADP into differentially loaded liposomes was measured. All plant APCs transported ADP in hetero-exchange with P<sub>i</sub> as well as in homo-exchange with ADP and no import occurred into non-loaded vesicles (Additional file 2: Figure S2). The rates of ADP transport (in exchange with P<sub>i</sub> or ADP) largely resemble the rates of the corresponding Mg<sup>2+</sup>-stimulated ATP transport (in exchange with P<sub>i</sub> or ATP) (Table 1; compare Additional file 2: Figure S2 and Fig. 1). Just like observed for ATP transport, all plant APCs favor the homo-exchange of ADP over the corresponding ADP/P<sub>i</sub> hetero-exchange and this preference is highly pronounced for AtAPC1 followed by AtAPC3 and finally AtAPC2 (Table 1). Moreover, comparison of the rates of ATP and ADP homo-exchanges with those of the corresponding P<sub>i</sub> hetero-exchanges (Table 1) suggests that AtAPC2 in contrast to AtAPC1 and 3 does not strongly discriminate between nucleotides or P<sub>i</sub> as internal counter exchange substrate. The ineffectiveness of non-loaded vesicles to induce significant import of ATP or ADP also demonstrates that vesicles do not allow carrier-independent passage of the labeled compounds.

**Calcium differentially affects ATP and ADP transport properties of the plant APCs**

Diverse physiological data indicate a Ca<sup>2+</sup>-dependent regulation of mitochondrial net adenine nucleotide passage [16–18, 39, 41]. In the native environment many factors such as activity of adenylate kinases, Ca<sup>2+</sup>-induced metabolic processes, the mitochondrial membrane potential, respiration, Mg<sup>2+</sup> complexation of ATP, etc. influence internal and external adenylate and P<sub>i</sub> pools and consequently also mitochondrial adenine nucleotide translocation in general [42–45].

Transport studies with reconstituted APCs might provide a suitable tool to overcome interfering metabolic and physiological effects and to study the impact of Ca<sup>2+</sup> on this process in more detail. However, it is important to mention that transport of reconstituted human SCaMC1 was not stimulated by Ca<sup>2+</sup> addition [12] and also AtAPC1-3 are already active in the absence of any Ca<sup>2+</sup> addition (Fig. 1 and Additional file 2: Figure S2). These findings suggest that Ca<sup>2+</sup> is not essentially required for carrier activation or that Ca<sup>2+</sup> contaminations exist in the buffer media. Determination of cations (by ion chromatography) revealed that in fact traces of both, Ca<sup>2+</sup> and Mg<sup>2+</sup>, are present in the media (~9 μM, respectively).

If Ca<sup>2+</sup> is essential for carrier activation and under the assumption that the proteoliposomes still contain a certain amount of inactive (Ca<sup>2+</sup>-free) APC proteins, an addition of extra Ca<sup>2+</sup> should result in transport stimulation. To investigate a possible Ca<sup>2+</sup>-induced increase in transport activation we performed uptake studies with and without 200 μM Ca<sup>2+</sup>. Elevated Ca<sup>2+</sup> availability generally stimulated nucleotide uptake of all three plant APCs (Table 2). This observation might point to a Ca<sup>2+</sup>-induced activation of previously inactive (Ca<sup>2+</sup>-free) carrier proteins. Studies with the two separately expressed subdomains (N-terminal domain and membrane spanning part) of the human SCaMC1 led to the conclusion that the N-terminal domain acts as a lid that either opens or closes the translocation pathway in response to Ca<sup>2+</sup> availability [22]. Given that Ca<sup>2+</sup> exclusively causes removal of the N-terminal domain and hence activation of previously closed carriers, the same degree of stimulation would be expected independent of the kind of substrate exchanged. However, direct comparison of Ca<sup>2+</sup> influence on different exchanges shows that for the reconstituted plant APCs
At 2+ is present (Figs. 1 and 2). With rising μ during plant APC me-

The different effects of Ca²⁺ on ATP and ADP transport properties indicate that besides its proposed function in cap removal and carrier activation Ca²⁺ fulfills an additional role in substrate transport/recognition.

Ca²⁺ effects override Mg²⁺ effects on ATP transport
To approach the function of Ca²⁺ during plant NPC-mediated transport it is important to keep in mind that ATP can form a complex with Mg²⁺ as well as with Ca²⁺ and it is thus imaginable that plant APCs are capable of ATP-Ca transport in vitro.

Table 3 Effects of 200 μM calcium on K_M-values of adenine nucleotide transport

The degree of stimulation is higher for ATP than for ADP or ATP-Mg uptake (Table 2).

We thus determined the apparent biochemical parameters of ATP/P, and ADP/ATP exchange for all three AtAPCs in more detail (Table 3). Velocity of transport of all recombinant carriers approached saturation with increasing ATP or ADP concentrations and conformed to simple Michaelis-Menten kinetics (Additional file 3: Figure S3). The individual AtAPC isoforms differed in their respective ADP affinities (AtAPC1: 180 μM, AtAPC2: 374 μM and AtAPC3: 72 μM) whereas the ATP affinities were more similar (ranging from 68 to 113 μM). Affinities of AtAPC1 for ATP and ADP remained more or less unaffected by Ca²⁺ addition whereas ATP affinities of AtAPC2 and AtAPC3 increased (1.6- and 2.0-fold) and ADP affinities decreased (1.4- and 1.9-fold), respectively. All AtAPC isoforms generally exhibit lower maximal velocities (V_max) for ATP than for ADP transport (Table 3). Since the V_max is proportional to the amount of actively transporting carrier proteins enhanced Ca²⁺-dependent activation of the APCCs should be reflected by an identical increase in the V_max of both, ADP and ATP transport. However, addition of extra Ca²⁺ caused only a moderate increase (by approximately 1.2- to 1.5-fold) in maximal ADP V_max but stimulated the respective ATP V_max (2.0- to 2.5-fold) of all three APCCs to a greater extend.

The different effects of Ca²⁺ on ATP and ADP transport properties indicate that besides its proposed function in cap removal and carrier activation Ca²⁺ fulfills an additional role in substrate transport/recognition.

Ca²⁺ effects override Mg²⁺ effects on ATP transport
To approach the function of Ca²⁺ during plant NPC-mediated transport it is important to keep in mind that ATP can form a complex with Mg²⁺ as well as with Ca²⁺ and it is thus imaginable that plant APCs are capable of ATP-Ca transport in vitro.

Comparison of Ca²⁺ effects on ATP and ATP-Mg transport indeed revealed interesting results that support this assumption. Mg²⁺ addition causes marginal (AtAPC2) to moderate (AtAPC1 and 3) increase in ATP transport when no extra Ca²⁺ is present (Figs. 1 and 2). With rising Ca²⁺ concentration the positive impact of Mg²⁺ becomes abolished and even reverted into a negative one (Fig. 2). More precisely, with higher Ca²⁺ concentrations (>10 μM AtAPC2; > 50 μM AtAPC1 and 3) the rates of ATP transport in absence of Mg²⁺ exceed the rates of the corresponding exchange in presence of Mg²⁺. Accordingly, in presence of Mg²⁺ higher concentrations of Ca²⁺ are apparently required to achieve ATP-transport saturation.

Table 2 Stimulation of the given exchanges by addition of 200 μM CaCl2

Determination of Ca²⁺-dependent stimulation (x-fold) was calculated according to the corresponding transport in absence of Ca²⁺. SE are always below 15 % of the given value.

| Exchange (import/export) | AtAPC1 | AtAPC2 | AtAPC3 |
|--------------------------|--------|--------|--------|
| ATP/P_1                  | 3.05   | 3.12   | 4.30   |
| ATP-Mg/P_1               | 1.67   | 2.75   | 1.94   |
| ATP/ATP                  | 2.65   | 3.39   | 3.62   |
| ATP-Mg/ATP               | 1.59   | 2.37   | 1.82   |
| ADP/P_1                  | 1.55   | 2.03   | 1.49   |
| ADP/ADP                  | 1.56   | 2.12   | 1.54   |
| ADP/ATP                  | 1.79   | 2.20   | 1.70   |

Accordingly, in presence of Mg²⁺ higher concentrations of Ca²⁺ are apparently required to achieve ATP-transport saturation.
was considerably stimulated by increasing Ca\(^{2+}\) concentrations (~3-fold). Moreover, the degree of Ca\(^{2+}\)-dependent stimulation and the general course of the corresponding transport basically resembled that of the full-length protein (Fig. 3, black squares). Investigation of ADP uptake into ATP loaded liposomes revealed slight transport stimulation of the full-length protein by low Ca\(^{2+}\) concentrations (~35 % at 50 to 100 \(\mu\)M Ca\(^{2+}\)), which approached saturation at higher concentrations (+60 %) (Fig. 3a, gray circles), whereas the corresponding transport of the truncated carrier version remained rather unaffected by moderate Ca\(^{2+}\) concentrations (+/- 10 % until 200 \(\mu\)M Ca\(^{2+}\)) and became stimulated only at higher Ca\(^{2+}\) concentrations (+50 %) (Fig. 3b, gray circles).

Although slight differences in the Ca\(^{2+}\)-impact are detectable, the higher influence of Ca\(^{2+}\) on ATP than on ADP import is apparently independent of the presence or absence of the N-terminal domain. This result verifies that the observed Ca\(^{2+}\)-dependent ATP transport stimulation does not primarily result from carrier activation and might rather be caused by increased ATP-Ca formation and substrate availability.

---

**Fig. 2** Ca\(^{2+}\)-impact on ATP transport via AtAPC1-3. Effect of rising Ca\(^{2+}\)-concentrations (0–500 \(\mu\)M) on transport mediated by recombinant AtAPC1 (a, b), AtAPC2 (c, d) and AtAPC3 (e, f). Transport of 50 \(\mu\)M [\(\alpha\)\(^{32}\)P]-ATP was conducted in absence (black rhombs) and presence of supplemental MgCl\(_2\) (gray rhombs). Transport was allowed for 5 min and is given in nmol mg protein\(^{-1}\) h\(^{-1}\). Ca\(^{2+}\)-dependent stimulation of ATP/P, hetero-exchanges (a, c, e) and ATP/ATP homo-exchanges (b, d, f). Non-loaded liposomes (non-filled rhombs; negative control) showed only marginal accumulation of ATP and the corresponding rates were unaffected by MgCl\(_2\) addition. Data represent mean values of three independent replicates, standard errors are given.
ATP but not ADP import of AtAPC2 requires the presence of divalent cations

Because full-length AtAPC2 already exhibits basic ATP/P\textsubscript{i} exchange activity without extra Ca\textsuperscript{2+} addition and particularly because ADP uptake becomes not highly stimulated by rising Ca\textsuperscript{2+}-concentrations (Fig 3), it might be assumed that the majority of reconstituted carriers is already opened/activated due to contaminating Ca\textsuperscript{2+}.

The cation chelator EGTA efficiently chelates Ca\textsuperscript{2+} (with significant higher affinity than to Mg\textsuperscript{2+}) and accordingly should remove residual Ca\textsuperscript{2+} from the medium. We thus used addition of EGTA to the transport medium to investigate whether and how Ca\textsuperscript{2+} depletion affects carrier activities. ATP/P\textsubscript{i} exchange of full-length AtAPC2 becomes significantly reduced by addition of 10 \textmu M EGTA and further increase of its concentration causes total inhibition (Fig 4a, black squares). Interestingly, a similar inhibitory effect was also observed for the truncated carrier version (Fig 4b, black squares). Given that the N-terminal domain forms a lid that virtually closes the translocation pathway when free Ca\textsuperscript{2+} is missing, efficient Ca\textsuperscript{2+}-removal should impede transport activity of AtAPC2 but not of the “uncapped” mutant. Moreover, ADP/ATP exchange of both, full-length and truncated, AtAPC2 variants remained more or less unaltered by EGTA addition (Fig. 4a and b, gray circles). Accordingly, Ca\textsuperscript{2+} removal from the medium did not cause inhibition of the overall transport capacity by deactivation of the reconstituted carrier.

Interestingly, transport via AtAPC2 was not only blocked by EGTA but also by the divalent cation chelator EDTA. Moreover, activity of the EGTA-inhibited carrier could be fully restored by either Ca\textsuperscript{2+} or Mg\textsuperscript{2+} (Fig. 5). However, when compared to Ca\textsuperscript{2+} higher concentrations of Mg\textsuperscript{2+} are required for transport reactivation/stimulation.

So far we cannot explain explicitly why solely ATP transport, but not general carrier activity, becomes inhibited by EGTA. It is imaginable that full-length AtAPC2 proteins are primarily or exclusively inserted in an inside-out orientation, exposing the N-terminal domain to the
liposomal interior. This orientation would clearly hinder EGTA access to the regulatory sites (EF-Hands). However, AtAPC2-proteoliposomes loaded with Pᵢ and 200 μM EGTA were still capable for ATP import (78 % of the corresponding EGTA-unaffected transport) (Additional file 5: Figure S5). Moreover, inhibition of ATP uptake into these EGTA-loaded liposomes by external EGTA as well as its (re)activation by 500 μM external Ca²⁺ were nearly identical when compared to standard AtAPC2-proteoliposomes lacking internal EGTA (Additional file 5: Figure S5).

Together, the obtained results indicate that ATP transport but not ADP or Pᵢ transport of AtAPC2 essentially requires the presence of divalent cations and this requirement is independent of the N-terminal domain and thus not connected to carrier activation.

**Plant APC2 can mediate Ca²⁺-transport in vitro**

The observed Ca²⁺ and EGTA effects on AtAPC2 activity led us to the conclusion that Ca²⁺ might act as an important co-substrate in ATP transport. To verify the proposed capacity of AtAPC2 for ATP-Ca transport in the liposomal system we performed uptake studies with 20 μM [⁴⁵Ca] and 100 μM non-labeled ATP. Preliminary analyses revealed that the read-out of the import rates was hampered due to the high degree of nonspecific [⁴⁵Ca]-interaction with the phospholipids at the liposomal surface (causing high radioactive background values). However, reduction of these non-specific background counts by removal of the vast majority of [⁴⁵Ca] from the liposomal surface was achieved by additional EGTA treatment of the vesicles subsequent to the uptake measurements (prior to vacuum filtration and washing). The correspondingly modified transport assay allowed determination of small but significant time dependent Ca²⁺ uptake by full-length and truncated AtAPC2.

Ca²⁺ uptake into Pᵢ loaded vesicles (Fig. 6a and b, black rhombs) always exceeded the corresponding rates obtained with non-loaded proteoliposomes (Fig. 6a and b, gray squares) indicating that Ca²⁺ accumulation is directly connected to the antiport activity of the carrier. The full-length protein exhibits higher Ca²⁺ transport rates and also the back-ground values of the non-loaded vesicles are enhanced when compared to the truncated version (compare Fig. 6a and b). So far it cannot be discriminated whether - albeit EGTA treatment - a certain amount of Ca²⁺ still binds to the N-terminal domain of recombinant AtAPC2 or/and the functionality of the truncated protein is generally slightly impaired.

Lastly, we analyzed effects of Mg²⁺ on Ca²⁺ import via recombinant AtAPC2. For this, Pᵢ loaded and non-loaded AtAPC2 proteoliposomes were incubated in transport medium containing 20 μM [⁴⁵Ca], 100 μM non-labeled ATP and increasing concentrations of Mg²⁺. [⁴⁵Ca] import into phosphate loaded vesicles became significantly reduced by Mg²⁺ whereas the corresponding rates of the non-loaded vesicles remained more or less unaffected by Mg²⁺ addition (Fig. 6c). Quite high amounts of Mg²⁺ (200 μM) are required to cause approximately half maximal transport inhibition whereas 25-fold excess of Mg²⁺ completely blocks Ca²⁺ uptake. Because of the generally low [⁴⁵Ca] transport rates of the truncated AtAPC2 reliable interpretation of the corresponding results obtained with this protein is complicated. Nevertheless, the tendency of Mg²⁺ impact on Ca²⁺ uptake generally resembles that of the full-length protein (Additional file 6: Figure S6). The obtained data suggest that Mg²⁺ competes with Ca²⁺ during ATP complex formation and thereby can reduce ATP-Ca availability and hence Ca²⁺-import via the reconstituted carrier.
Discussion

Transport capacities of plant APCs allow energy exchange as well as net adenine nucleotide provision

Diverse biological conditions, such as ATP-loading during mitochondrial biogenesis or physiological and environmental changes, require modulation of the mitochondrial adenine nucleotide pool size [9, 17, 18, 46]. During the past decades net influx or efflux of adenine nucleotides into or out of the organelle as well as the involved carriers have been well studied in mammals and yeast [9, 11, 12, 14–18, 46]. However, much less is known about these processes in plants.

It is quite obvious that also plant mitochondria have to adapt the adenine nucleotide concentration in the mitochondrial matrix in accordance to the respective metabolic demands. Already in the 1970s isolated corn and cauliflower mitochondria were shown to exhibit (carboxy)tractylloside insensitive (AAC independent) uptake of adenine nucleotides [26–28]. In the beginning, net import of ADP into plant mitochondria was identified to occur via exchange with P\textsubscript{i} [31]. Later on, ADP transport was shown to be influenced by Mg\textsuperscript{2+} and Ca\textsuperscript{2+} and it was suggested that exogenous rather than endogenous P\textsubscript{i} drives net ADP uptake [29]. These inconsistencies might be due to the fact that mitochondria harbor various carriers and enzymes directly or indirectly involved in adenine nucleotide transport and metabolism and that these proteins are differently affected by the respective test conditions and metabolic states of the organelle.

Arabidopsis thaliana encodes three MCF proteins (AtAPC1-3) that represent promising candidates for net adenine nucleotide transport. First of all, AtAPC1-3 exhibit significant amino acid similarities to APCs from animals or yeast and contain the characteristic N-terminal domain with EF-hand motifs (Additional file 7: Figure S7 and Additional file 8: Figure S8). Secondly, these proteins can compensate the growth defect of yeast Δsal1p mutants inhibited in AAC mediated transport [32]. Thirdly, transport assays performed in this work with the reconstituted, recombinant carriers revealed that AtAPC1-3 act in a strict antiport mode.
(Fig. 1, Additional file 2: Figure S2); they can catalyze homo-exchanges of ATP and ADP as well as ATP/ADP hetero-exchange but most importantly also ATP and ADP hetero-exchange with P$_i$ in vitro (Fig. 1, Additional file 2: Figure S2, Tables 1, and 3). The latter capacity was also shown recently in a study by Palmieri and coworkers that was published while this manuscript was in revision [47]. Based on the in vitro characteristics growth-restoration in the yeast complementation assay by the three AtAPC isoforms [32] can be attributed to their capacity for net adenine nucleotide supply (complementation of Sal1p activity) and/or for energy provision (complementation of AAC activity).

Plant mitochondria possess a high affinity ATP uptake system that is sensitive to AAC-specific inhibitors and a low affinity ATP uptake system that apparently does not involve AAC activity [30]. Biochemical characterization of single isoforms suggest that AAC proteins mediate the high affinity ATP transport [48] whereas APCs catalyze or contribute to the low affinity ATP transport (Table 3) [47].

Interestingly, APC genes show more or less ubiquitous expression with highest rates in growing tissues of enhanced mitochondrial propagation (Aramemnon, BAR eFP browser; [49, 50]). The recent work by Palmieri and coworkers showed that the promoter of Atapc1 exhibits enhanced activity when compared to the remaining two APC isoforms [47]. Moreover, expression of specific isoforms (Aramemnon, GENEVESTIGATOR [49, 51]) is induced by growth-promoting plant steroids (brassinosteroids) or in response to abiotic stressors, like hypoxia or phosphate limitation; conditions assumed to be associated with altered mitochondrial metabolism/respiration [45, 47, 52–54]. In future studies it will be interesting to determine whether specific developmental stages or stress situations characterized by enhanced or reduced APC expression correlate with the establishment or alteration of the mitochondrial adenine nucleotide pool.

### Substrate preferences and impact of divalent cations on transport

The fact that recombinant AtAPC3 and AtAPC1 apparently prefer homo-exchanges of ATP and ADP over the corresponding hetero-exchanges with P$_i$ (Fig. 1, Additional file 2: Figure S2) might be indicative of transport reduction due to unfavorable charge imbalances generated in the liposomes by the electrogenic hetero-exchange. Similar to net ATP uptake by yeast and mammalian mitochondria [11, 15, 16, 18] ATP transport of AtAPC1 and AtAPC3 is markedly stimulated by Mg$^{2+}$ (Fig. 1, Table 1). This stimulation occurs during homo- and hetero-exchange and suggests that AtAPC1 and AtAPC3 generally prefer ATP-Mg$^{2+}$ over ATP$^{4-}$ as import substrate independent of the generation of charge imbalances.

In contrast to AtAPC1 and AtAPC3, rates of homoe- and hetero-exchange of recombinant AtAPC2 are quite similar (Fig. 1, Additional file 2: Figure S2) and ATP uptake was only slightly enhanced by Mg$^{2+}$ addition (Fig. 1c and d). These observations suggest that either a strong preference of AtAPC2 for P$_i$ as exchange substrate compensates possible negative effects of the charge imbalance of ATP/P$_i$ (and ADP/P$_i$) hetero-exchange or that hetero-exchange with P$_i$ is not electrogenic at all. Interestingly, ATP transport of AtAPC2 was totally inhibited by EGTA or EDTA and could be restored by Mg$^{2+}$ or Ca$^{2+}$ (Fig. 5). This result strikingly argues for the requirement of divalent cations for ATP translocation. Whether this is due to their function as co-substrate and/or as effectors of the carrier protein cannot be unambiguously stated yet.

In contrast to our studies, Palmieri and coworkers investigated the capacity of ATP-Mg to act as export and not as import substrate and under those conditions ATP-Mg transport is rather unfavorable when compared to ATP [47]. Summarily, the current data therefore suggest that the plant APCs possess different substrate preferences at their exterior and interior side (Fig. 1, Table 1) [47].

Although Ca$^{2+}$-dependent activity regulation of human and yeast APCs has been well known for a long time, first insights into the mechanistic principle were only gained recently. Sophisticated interaction studies with human SCaMC1 suggest that in absence of Ca$^{2+}$ the quite flexible N-terminal domain caps the transmembrane part whereas Ca$^{2+}$-binding turns the N-terminal domain into a more rigid state which leads to its dissociation and opening of the translocation pore [21, 22]. Superimposition of the corresponding regions in a structural alignment visualizes a high degree of conservation among the N-terminal domains of plant APCs and human SCaMC1 (Fig. 7). These structural similarities as well as computer based docking analyses (Additional file 8: Figure S8) suggest that the N-terminal domains of the plant APCs also interact with four Ca$^{2+}$ ions. Moreover, amino acid sequence similarity to Sal1p and human SCaMC isoforms suggest that plant APCs are likewise regulated by Ca$^{2+}$ (Additional file 7: Figure S7, Fig. 7).

The fact that reconstituted APC isoforms from human [12] and A. thaliana were already active without extra Ca$^{2+}$-addition led to the assumption that Ca$^{2+}$ contaminations in the buffer media were sufficient for carrier activation. Because increase in Ca$^{2+}$-concentrations resulted in transport stimulation of all recombinant AtAPC isoforms one might conclude that under the reconstitution conditions a mix of active and non-active carries occurs and addition of Ca$^{2+}$ can thus activate additional carriers (Fig. 2). However, the rates of Ca$^{2+}$-stimulation were not
identical and varied depending on the kind of substrate transported (Table 2).

Assuming that Ca$^{2+}$ exclusively operates in carrier activation by displacement of the N-terminal domain from the translocation pathway we would expect the same degree of (i) Ca$^{2+}$-dependent transport stimulation, (ii) $V_{\text{max}}$ increase (proportional to the amount of functional carriers), and (iii) transport reduction by Ca$^{2+}$-depletion (with EGTA) independent of the exchanged substrates. Moreover, truncation of the N-terminal domain should cause constantly active carriers that are no longer influenced by Ca$^{2+}$. However, the data obtained in this work suggest that this is not the case. We therefore hypothesize that in the in vitro system ATP-Ca acts as substrate of the plant APCs and is even favored over ATP-Mg or free ATP. By contrast, ADP-Ca seems to be rather discriminated against when compared to free ADP. Ca$^{2+}$-induced alterations of the apparent transport affinities most likely reflect these specific substrate preferences of the respective APC isoforms e.g. higher preference for ATP-Ca (when compared with the Mg-complexed or free ATP) and lower preference of ADP-Ca (when compared to free ADP) (Table 3). Accordingly, Ca$^{2+}$ complexation of ATP enhances and that of ADP reduces the amount of favored substrates and by this the respective transport capacity of the reconstituted protein.

It is also imaginable that in the liposomal system, Ca$^{2+}$ co-transport with ATP prevents charge accumulation of the ATP/P$_{i}$ hetero-exchange and with ADP$^{3-}$ (ADP-Ca$^{4+}$) enhances the imbalance caused by the ADP/ATP hetero-exchange. In addition, effects of EGTA, EDTA, Mg$^{2+}$ and Ca$^{2+}$ on ATP transport inhibition, stimulation or reactivation suggest a competition between these cations during complex formation and provide further evidences for ATP-Ca as a potential in vitro substrate of recombinant plant APCs (Table 2 and Figs. 3, 4, 5). We conclude that the influence of Ca$^{2+}$ on transport by the reconstituted APCs is a consequence of diverse factors, such as substrate preferences, charge accumulation/compensation and competition with Mg$^{2+}$ during complex formation.

Transport characteristics obtained with AtAPC2 and the N-terminally truncated version support the assumption that ATP-transport stimulation by Ca$^{2+}$ is not (or not exclusively) caused by activation of previously inactive (Ca$^{2+}$-free) carriers. ATP transport of both, the full-length carrier and the truncated version, can be stimulated by Ca$^{2+}$ and inhibited by EGTA whereas ADP transport was not significantly affected (Figs. 3 and 4). These results verify that solely ATP but not ADP transport activity is highly dependent on the presence of Ca$^{2+}$ and that removal of this cation did not cause carrier deactivation in general. The ineffectiveness of EGTA in the inhibition of total transport activity is surprising. The possibility that plant APCs are generally not regulated in a Ca$^{2+}$-dependent manner is apparently not applicable. Important structural similarities of the plant, yeast and mammalian isoforms are suggestive for a similar regulatory principle but most importantly, a corresponding regulation could be demonstrated in the recent study by Palmieri and co-workers [47]. It remains unclear whether in our in vitro system the functionality of the N-terminal domain of the recombinant AtAPC2 is somehow impaired or its affinity for Ca$^{2+}$ is higher than that of EGTA. However, the possibility that insight-out orientation of reconstituted AtAPC2 and hence inaccessibility of the N-terminal domains caused ineffectiveness of EGTA in transport inhibition can be ruled out since proteoliposomes internally loaded with EGTA were still capable to import ATP in exchange with P$_{i}$ (Additional file 5: Figure S5).

The fact that external but not internal EGTA caused inhibition of AtAPC2 mediated ATP import in exchange with P$_{i}$ demonstrates that ATP but not P$_{i}$ transport requires the presence of Ca$^{2+}$ (or divalent
cations). Moreover, this observation also demonstrates that the chelator at the liposomal interior is apparently physically separated from Ca\(^{2+}\) at the exterior (at least during the analyzed time span) which indicates that both, EGTA and Ca\(^{2+}\), do not pass the lipid barrier freely.

Notwithstanding or even because of the missing Ca\(^{2+}\)-dependent regulation, we were able to identify the in vitro function of Ca\(^{2+}\) as co-substrate with the applied system.

Although uptake studies with α[^32P]-ATP provided evidence for a possible ATP-Ca transport it would still have been imaginable that Ca\(^{2+}\) stimulates transport of unchelated ATP and impedes ATP-Mg transport in a different way. However, the specifically adapted uptake assay using \[^{45}Ca\] provided a direct proof that ATP-Ca is de facto transported via reconstituted (Fig. 6). Time dependent uptake of \[^{45}Ca\] via AtAPC2 is tightly connected to its antiport activity because P, loaded proteoliposomes accumulated higher amounts of \[^{45}Ca\] than non-loaded vesicles. Competition experiments further verified that ATP-Ca transport is favored over ATP-Mg transport in vitro since quite high concentrations of Mg\(^{2+}\) are required to reduce ATP-transport associated Ca\(^{2+}\) uptake (Fig. 6c, Additional file 6: Figure S6). When compared to full-length AtAPC2 the N-terminally truncated carrier shows reduced Ca\(^{2+}\) import capacity (Fig. 6b). Whether absence of the N-terminal domain affects transport activity directly or rather indirectly (via impairments in refolding and membrane insertion) cannot be deduced from these experiments.

Further studies with the reconstituted proteins as well as with transgenic APC plants and isolated mitochondria will be required to completely decipher, evaluate and compare in vitro and in vivo characteristics of APC proteins. Moreover, it will be interesting to determine the stoichiometry of the ATP and Ca\(^{2+}\) co-transport. Preliminary estimation suggests that these substrates are not transported in a 1:1 stoichiometry. However, in this context it is important to mention that uptake assays had to be adapted to make Ca\(^{2+}\) transport determination feasible and furthermore that Ca\(^{2+}\) and Mg\(^{2+}\) contaminations of the media have to be considered. Therefore, in future studies we want to further optimize Ca\(^{2+}\)-transport measurements in liposomes and intent to decipher the impact of divalent cations on AtAPC1-3 function in vivo.

Can ATP-Ca transport via plant APCs occur in vivo?

SCaMCs as well as yeast Sal1p seem to prefer ATP-Mg whereas our initial studies indicate that at least one of the AtAPC isoforms clearly favors ATP-Ca over both, ATP-Mg and ATP, as import substrate in the liposomal system. Due to the high structural similarity to ATP-Mg it is - from a biochemical point of view - not surprising that at least certain APCs can in principle accept ATP-Ca as substrate in vitro. However, the intriguing question arises whether ATP-Ca formation and correspondingly APC mediated Ca\(^{2+}\)-transport can and will take place under physiological conditions. Generally, ATP-Ca formation is a rather unlikely phenomenon in plant cells. The concentration of free Ca\(^{2+}\) is usually low when compared to Mg\(^{2+}\), which represents a dominating divalent cation and also is Mg\(^{2+}\) favored over Ca\(^{2+}\) in ATP-complex formation. However, one could envision specific situations that might support possible ATP-Ca formation in close proximity to the carrier.

Although plant mitochondria contribute to Ca\(^{2+}\) storage, the majority of internal Ca\(^{2+}\) is probably transiently fixed as amorphous phosphate precipitate and thus the resting concentration of free Ca\(^{2+}\) in the matrix only slightly exceeds that of the cytosol (200 nM vs. 100 nM) [55–57]. Moreover, due to high Mg\(^{2+}\) concentrations within plant mitochondria ATP is nearly completely complexed with Mg\(^{2+}\), which argues against any potential ATP-Ca formation in the matrix [45]. Although lower Mg\(^{2+}\) levels in the cytosol increase the accessibility of free ATP, it is unclear whether conditions or microdomains of high Ca\(^{2+}\) availability at the mitochondrial surface might allow ATP-Ca formation [55, 58–63]. In the liposomal system Ca\(^{2+}\) uptake via AtAPC2 was low and completely blocked by 25-fold excess of Mg\(^{2+}\). If these characteristics (the biochemical properties in combination with a high Mg\(^{2+}\) to Ca\(^{2+}\) ratio next to the carrier) also represent the in vivo situation, ATP-Ca transport via plant APCs is highly unlikely to occur.

Although, a direct role of plant APCs in ATP-Ca transport is therefore arguable, recent data suggest an indirect function of a mammalian isoform in Ca\(^{2+}\) translocation. SCaMC3 was shown to physically interact with the (low affinity) Mitochondrial Calcium Uniporter (MCU) and lack of SCaMC3 apparently decreases ATP and Ca\(^{2+}\) import into mitochondria [24, 64]. Accordingly, SCaMC3 was supposed to represent an important component of the mitochondrial Ca\(^{2+}\) uptake system, a supercomplex formed by channels and carriers in microdomains for enhanced Ca\(^{2+}\)-sensitivity [64]. Whether certain plant APC isoforms fulfill a function related to that described for SCaMC3 is unclear, however, physical proximity to proteins involved in Ca\(^{2+}\) release might be advantageous to guarantee fast Ca\(^{2+}\)-dependent activation and response of plant APCs.

Conclusions

Determination of the biochemical characteristics of three putative APC isoforms from A. thaliana in the liposomal system revealed that the recombinant carriers mediate ATP, ADP and phosphate exchange. Accordingly, plant mitochondria harbor a subset of carriers capable of net
adenine nucleotide translocation, however in contrast to yeast and mammalian orthologs they show no high preference for ATP-Mg as import substrate. Surprisingly, we instead obtained evidence for a possible ATP-Ca transport by the reconstituted plant APCs in the liposomal context but it is arguable that physiological Mg$^{2+}$ and Ca$^{2+}$ concentrations most likely prevent ATP-Ca formation and its subsequent transport in vivo. Although we were not able to detect EF-hand based Ca$^{2+}$-dependent carrier regulation, this was shown recently to exist in plant APCs [47]. Summarily, the current data suggest that low Ca$^{2+}$ concentrations regulate activity of plant APCs via EF-hands of the N-terminal domain whereas high Ca$^{2+}$ concentrations can induce its own transport as co-substrate of ATP in vitro. While this study deepens our knowledge about mitochondrial net nucleotide transport of plants it also gives rise to new intriguing questions. In the future, it is important to investigate the in vivo function of plant APCs and the impact of divergent cations on the corresponding transport.

Additional file 5: Figure S5. Impact of internal EGTA on ATP transport via AtAPC3. Uptake of 50 µM [$^{32}$P]-ATP into proteoliposomes loaded with P (black bars) or P$_1$ (gray bars) was set to 100% (control). Inhibitory and stimulatory effects of externally added EGTA (50 µM) and CaCl$_2$ (500 µM) on the corresponding transport rates were calculated accordingly. Reactivation of transport inhibited by external EGTA was induced by addition of 500 µM CaCl$_2$. Transport (inhibition as well as activation) was allowed for 10 min. Data represent net values (ATP/P, exchange minus background values of non-loaded proteoliposomes) and are the mean of at least three replicates. Standard errors are indicated. (PDF 252 kb)

Additional file 6: Figure S6. Effects of rising MgCl$_2$ concentrations on ATP transport via the N-terminally truncated AtAPC2. Transport of 200 µM [$^{32}$P]-Ca$^{2+}$ into P, loaded dark gray bars) and non-loaded (light gray bars) proteoliposomes was allowed for 10 min (given as nmoL mg protein$^{-1}$ h$^{-1}$). The transport medium was supplemented with 100 µM non-labeled ATP and the indicated MgCl$_2$ concentrations. Data represent mean values of three independent replicates. Standard errors are indicated. (PDF 102 kb)

Additional file 7: Figure S7. Alignment of APC proteins from different organisms. Amino acid sequence alignment of APCs from A. thaliana (AtAPC1-3 [GenBank:At5g61810; At5g51050; At5g07320]), S. cerevisiae (Sac1p [GenBank:YNL083w]) and human (hSCAMC1-3 [GenBank:SLC25A24; SLC25A25; SLC25A28]) using ClustalW2 (http://www.ebi.ac.uk). To allow easy detection of the N-terminal extension mitochondrial AAC2 from S. cerevisiae (ScPET9 [GenBank:YBL030C]) was included as a representative MCF protein. Shading of conserved amino acid residues was performed with Boxshade at the Swiss EMBl server (http://www.ch.embnet.org/index.html). Residues of the N-terminal domains of AtAPC1-3 proposed to be involved in Ca$^{2+}$-interaction are highlighted by different colors. Residues predicted by Scanprosite (http://prosite.expasy.org/scanprosite) are marked in green and by molecular Ca$^{2+}$ docking analyses with AutoDock vina (see also Additional file 8: Figure S8) are marked in orange. Car$^{2+}$-interacting residues predicted by Scanprosite and molecular docking studies are marked in yellow. EF-hands I and II (green boxes), II (orange boxes) exhibit lower support for Ca$^{2+}$-interaction (Scanprosite) than EF-hands II and IV (green boxes). (PDF 476 kb)

Additional file 8: Figure S8. Docking poses of Ca$^{2+}$ ions within the N-terminal domains of AtAPC1-3. Docking analyses and structural superimposition with human SCA1C1 (SLC25A24). Three-dimensional homology models of the N-terminal domains of AtAPC1 (residues 34-189, green), AtAPC2 (residues 38-194, yellow) and AtAPC3 (residues 35-189, orange) were built using HHpred server and Modeeller using the crystal structure of the Ca$^{2+}$-bound state of the N-terminal domain of human SCA1C1 (blue as template (PDB ID: 4NSX). The four EF-hand motifs putatively involved in Ca$^{2+}$ binding are marked in dark blue (A, C, E). Docking poses of Ca$^{2+}$ ions are shown for AtAPC1 N-term (A), AtAPC2 N-term (C) and AtAPC3 N-term (E) with residues putatively interacting with Ca$^{2+}$ marked in red. These residues were chosen either based on docking or Scanprosite results (http://prosite.expasy.org/scanprosite). For the molecular docking analyses, Ca$^{2+}$ ions and the N-terminal domains of AtAPC1-3 were prepared using Autodock Tools 1.5.6. After determination of the search space, the ions were docked into the structures using Autodock vina. The best binding poses for Ca$^{2+}$ were selected with respect to the total energy and EF-hand positions. Structural superimposition of AtAPC1 (B, AtAPC2 (D) and AtAPC3 (F) with SCA1C1 (blue) and Ca$^{2+}$ ions within this protein (blue spheres) was carried out using PyMOL (version 1.3) (PDF 298 kb)

Competing interests
The authors declare that they have no competing interests.

Authors’ contributions
IH, HEN and UCO contributed to the conception of the study. AL, ML and IH designed the experiments. AL and ML performed cloning and expression of the carriers in the heterologous system. AL and ML supervised transport measurements and functional characterization of the carriers. SNW
performed amino acid sequence analyses and generated three-dimensional models. AL, ML, SNW and IH collected the data and AL, HEN, UCV and IH performed data interpretation. IH wrote the manuscript and was supported by UCV and HEN. All authors read and approved the final manuscript.

Authors’ information
Not applicable

Availability of data and materials
Not applicable

Funding
The project was financially supported by the Deutsche Forschungsgemeinschaft (Reinhard Koselleck-Grant). Work in the lab of UCV was supported by the Deutsche Forschungsgemeinschaft (Center for Integrated Protein Science Munich, CPISM and VO656/5-1).
