I. INTRODUCTION

The study of frustration in magnetism has been a very active field of research in the recent past, both theoretically and experimentally. While experimentally-realizable frustrated magnets typically have a closer correspondence to quantum (i.e., Heisenberg or XY) spin models than to classical, Ising-like ones, their behavior turns out to be rather intricate. Thus, theoretical and/or numerical investigation of frustrated classical spin systems may, by virtue of their simplified character, help unravel some basic features which are common to frustrated magnets in general.

In this paper we investigate two-dimensional spin-1/2 Ising systems on a square lattice with first- and second-neighbor couplings, both antiferromagnetic, in the presence of a uniform magnetic field. The Hamiltonian is given by:

\[ H = J_1 \sum_{\text{NN}} \sigma_i \sigma_j + J_2 \sum_{\text{NNN}} \sigma_i \sigma_j - H \sum_i \sigma_i, \]  

where \( J_1, J_2 > 0 \), NN and NNN stand respectively for next-neighbor and next-nearest-neighbor pairs, and \( \sigma_i = \pm 1 \). Here, all fields, coupling strengths and temperatures are given in units of \( J_1 \), unless otherwise stated. We have kept \( J_2 = 1 \) in all calculations reported in this work, except at the end of Sec. [IIA] where \( J_2 = 2 \) and 0.75 were briefly considered (both for \( H = 0 \)).

In line with the initial considerations given above, this may be considered a classical approximation for the \( J_1 - J_2 \) (Heisenberg) model \[2,3]. Nevertheless, as shown in the following, the model described by Eq. [4] exhibits intricate features of its own, several of which are not fully understood so far. Depending on the relative strength of the associated parameters, such setup of competing interactions can generate various types of ordered phases at low temperature; more often than not, the transitions between these and the high-temperature (paramagnetic) state do not belong to the standard Ising universality class \[3,4].

The problem studied here has been analyzed by several numerical techniques in the past; Refs. [3] and [4] provide excellent summaries of earlier work, as well as illustrations of the use of up-to-date Monte-Carlo (MC) simulation techniques for this case.

We use transfer-matrix (TM) methods \[5\], in conjunction with finite-size scaling \[6\] and conformal invariance \[7\] concepts, to determine the location of the phase boundaries of systems described by Eq. [1], and the universality classes of the associated phase transitions. TM methods, especially in the strip geometry used in this work, are to some extent complementary to MC simulations, in that they provide straightforward procedures for evaluation of the conformal anomaly, or central charge \[8\], as well as the decay-of-correlations exponent \( \eta \) (via the amplitude-exponent relationship \[9\]). Both quantities play an important role in the identification of the universality classes pertaining to phase transitions in two-dimensional systems, and neither is directly accessible via MC methods (although direct estimates of \( \eta \) can be produced by following the decay of spin-spin correlations with distance in an MC context, no simple relationship applies, such as the one given by conformal invariance on strips \[10\]). On the other hand, similarly to MC techniques, TM calculations also provide estimates of critical temperatures, specific heats, magnetizations, and susceptibilities.

In Section [II] we recall the calculational methods used, as well as the finite-size scaling concepts and techniques
employed in the analysis of our results. Our numerical results for \( H = 0 \) are given in Section "A" and those for \( H \neq 0 \) in Section "B". Finally, in Sec. "C" concluding remarks are made.

II. CALCULATIONAL METHOD AND FINITE-SIZE SCALING

We set up the TM on strips of width \( N \) sites, with periodic boundary conditions across. The coordinate axes coincide with the directions of the first-neighbor bonds. We used \( 4 \leq N \leq 22 \). For comparison, earlier TM studies of this problem \cite{10, 11} could only reach \( N = 12 \). For the case \( J_2 = 1/4 \) in zero external field, results for \( N \leq 18 \) are available \cite{12}.

With \( \lambda_1, \lambda_2 \) being the two largest eigenvalues (in absolute value) of the TM, the dimensionless free energy per site is given by \( f_N(T) = N^{-1} \ln \lambda_1 \), while \( \kappa_N(T) = \ln |\lambda_1/\lambda_2| \) is the inverse correlation length on a strip of width \( N \) sites \cite{5}.

It must be stressed that we do not make any assumptions about symmetry properties of the TM’s eigenvectors. Starting from the full set of \( 2^N \) basis vectors, the eigenvector \( |v_1\rangle \), corresponding to \( \lambda_1 \), is isolated by the power method, while \( |v_2\rangle \) is again extracted via the power method, combined with repeated Gram-Schmidt orthogonalization to \( |v_1\rangle \). This way we make sure that the most strongly diverging correlation length is evaluated, that is, the one which truly corresponds to the order parameter for the transition under scrutiny. This is especially relevant in the present case, where critical lines corresponding to order parameters of differing symmetries can become very close (see Section "B" below).

Here we assume that the transition is always of second order, which is implicit in the statements made in the preceding paragraph. By now this seems out of doubt, at least for \( J_2 \geq 1 \) which is the parameter range of interest here \cite{3, 4}. For fixed \( J_2 \) and \( H \), say, we locate the approximate (\( N \)-dependent) critical temperature \( T_N^c \) by solving the basic equation of the phenomenological renormalization group (PRG) \cite{5}:

\[
N\kappa_N(T) = N'\kappa_{N'}(T) .
\]

Depending on the shape of the critical curve, it may be more convenient to keep \( T \) fixed and vary \( H \), in which case the critical behavior is expressed in terms of \( |H - H_c| \), and Eq. (2) gives \( H_N^c \). The strip widths \( N \) and \( N' \) are to be taken as close as possible for improved convergence of results against increasing \( N \). In order to obey ground-state symmetries, here we used only even \( N \), \( N' \), so \( N' = N - 2 \). For \( H = 0 \) and \( J_2 < 1/2 \), in which case the ordered phase is Néel-like \cite{4}, one can use both odd and even \( N \); indeed, good results are found from PRG with \( N' = N - 1 \) in that region \cite{12}. For \( J_2 > 1/2 \), we found that: (i) the latter procedure does not give physically meaningful solutions for Eq. (2); and (ii) although PRG with both \( N \) and \( N' \) odd gives the same limiting \( T_c \) with \( N \to \infty \) as when both strip widths are even (albeit with much slower convergence), estimates of quantities other than the critical temperature are unreliable.

Estimates of the thermal exponent \( y_T = 1/\nu \) are given by \cite{5}:

\[
y_T = 1 + \frac{\ln(\kappa'_N/\kappa_N)}{\ln(N/N')} .
\]

where \( \kappa'_N, \kappa_N \) are temperature derivatives of the inverse correlation lengths, taken at \( T_N^c \). Finite-\( N \) estimates of the exponent \( \eta \) are given by the conformal invariance relation \cite{5}:

\[
\eta_N = \pi^{-1} N \kappa_N(T_N^c) .
\]

The convergence of finite-\( N \) approximants given by Eqs. (2), (3), and (4) towards their \( N \to \infty \) values has been extensively discussed \cite{13, 14, 15}. For (unfrustrated) Ising-like systems on strips with periodic boundary conditions across, the rate of convergence goes like

\[
X_N - X_\infty = a N^{-\omega} ,
\]

with \( \omega \approx 3 \) for \( X = T^* \), and \( \omega \approx 2 \) for \( X = y_T \) (for some simple cases, this can be shown analytically \cite{13, 16, 17}). By taking sets of three successive finite-\( N \) estimates, one can use \( \omega \) as an adjustable parameter in Eq. (5), and produce a new, shorter, sequence which can then be iterated again, and so on. Such iterated three-point fit technique can produce very accurate final estimates of critical quantities \cite{14, 18, 19}.

Once \( T_c \) is found, as described above, to good accuracy (or if its exact value is known, for example via duality arguments \cite{18}), sequences of assorted quantities can be evaluated at the extrapolated critical point, for increasing \( N \). From these, one can usually extract estimates of critical exponents which converge faster and more smoothly than if the calculations were done at the respective pseudo-critical temperatures \( T_N^c \) \cite{13, 20}. One is interested in (per site) specific heats, susceptibilities, and magnetizations, which behave as \cite{6}:

\[
C_N(T_c) = C_0 + a_C N^{\alpha/\nu} ;
\]

\[
\chi_N(T_c) = a_N N^{\gamma/\nu} ;
\]

\[
m_N(T_c) = a_m N^{\beta/\nu} .
\]

Both \( C_N \) and \( \chi_N \) are found from suitable second derivatives of the free energy \cite{18}. The exponent ratio \( \alpha/\nu \) can then be extracted from three-point fits of sequences of \( C_N \), as explained in connection with Eq. (5). For \( \gamma/\nu \), one initially obtains a sequence of exponent estimates via two-point fits of susceptibility data, and then proceeds to extrapolating such a sequence via three-point fits \cite{18}.

The spontaneous magnetization \( m_N \) is difficult to calculate in a finite-size scaling context, because it is identically zero for a finite system. For quantum chains at \( T = 0 \) this problem can be overcome \cite{21}, by exploiting the fact that there the largest eigenvalue of the TM gives
the internal energy: in a first-order degenerate perturbation scheme, appropriate consideration of non-diagonal matrix elements enables one to extract the magnetization in the zero-field limit. For classical spins on strips, the corresponding eigenvalue of the TM gives the free energy instead, and the perturbation-theory procedure used for quantum systems \[21\] cannot be translated to our case.

In this work we estimated the finite-size magnetization exponent \(\beta/\nu\) by calculating the average squared magnetization per column at \(T_c\), \(\langle M^2 \rangle\). Considering, for example, a ferromagnet, denoting by \(\sigma \equiv \{\sigma_1 \cdots \sigma_N\}\) the \(2^N\) column basis states, and with \(\tilde{\psi}(\sigma)\), \(\psi(\sigma)\) being respectively the dominant left and right eigenvectors of the TM, one has \[2\]:

\[
\langle M^2 \rangle = \frac{\sum_\sigma \tilde{\psi}(\sigma) \left( \sum_{i=1}^N \sigma_i \right)^2 \psi(\sigma)}{\sum_\sigma \psi(\sigma) \psi(\sigma)}. \tag{7}
\]

At the critical point, one should have:

\[
\frac{1}{N} \langle M^2 \rangle^{1/2} \sim N^{-\beta/\nu}. \tag{8}
\]

For a square-lattice antiferromagnet with only first-neighbor interactions, \(\sigma_i\) in Eq. (7) must be replaced by \((-1)^i \sigma_i\), so the staggered character of the order parameter is properly taken into account. The corresponding adaptation for the system of interest here is discussed in Section III below. We tested this procedure, with the uniform (or staggered) version of the magnetization, on the following square-lattice Ising systems: (i) ferromagnet with nearest-neighbor couplings only; (ii) ferromagnet with first- and second-neighbor interactions, \(J_2 = 1\); and (iii) antiferromagnet with first- and second-neighbor interactions, \(J_2 = 1/4\) (for which the ordered state is Néel-like \[12\]). In all three cases, \(T_c\) is known either exactly or to a very good approximation, and the transition is in the Ising universality class \[12\] so \(\beta/\nu = 1/8\). In order to gauge the likely systematic errors for our intended final application (see Section III), we considered \(4 \leq N \leq 22\), and only even \(N\). All resulting sequences gave estimates of \(\beta/\nu\) monotonically growing with \(N\), pointing to extrapolated values between 0.1240 and 0.1247, so the systematic error is less than 1% for this range of \(N\).

Another quantity of interest to be calculated at \(T_c\) is the conformal anomaly \(c\), given by the \(N^{-2}\) finite-size correction of the critical free energy per site \[8\]. For the present case of strips with periodic boundary conditions across, one has:

\[
f_N(T_c) = f_0 + \frac{\pi c}{6N^2} + \mathcal{O}(N^{-4}). \tag{9}
\]

While models with \(c < 1\) are associated with universality classes with fixed values of the critical exponents, those with \(c \geq 1\) can have continuously varying exponents \[22\]. As shown below, there are strong indications that the model studied here belongs to the latter category (for \(H = 0\), this has already been pointed out in Ref. \[24\]). Additionally, one can both double-check the robustness of extrapolations of \(T_c\) and \(g_T\) from Eqs. (2) and (3), as well as investigate the other quantities of interest, by scanning the neighborhood of the critical point with the help of finite-size scaling ideas \[8\]. Taking, for instance, \(\eta_N(T) \equiv \pi^{-1} N N_T(N)\), and allowing for corrections to scaling, we write \[25\] and \[26\]:

\[
\eta_N(T) = f(u) + N^{-\omega} g(u), \quad u \equiv N^{1/\nu} (T - T_c). \tag{10}
\]

where \(\omega > 0\) is the exponent associated with the leading irrelevant operator [see Eq. (3)]. Close enough to \(T_c\), the scaling functions in Eq. (10) should be amenable to Taylor expansions. One has:

\[
\eta_N(T) = \eta + \sum_{j=1}^{j_m} a_j u^j + N^{-\omega} \sum_{k=0}^{k_m} b_k u^k, \tag{11}
\]

where \(\eta\) is to be compared with the \(N \to \infty\) extrapolated value of the \(\eta_N\) of Eq. (4).

One looks for values of \(T_c\), \(\nu\), \(\omega\) and the \(\{a_j, b_k\}\) which optimize data collapse upon plotting \(\eta_T(T) - N^{-\omega} g(u)\) against \(u\). In practice, good fits are generally found with \(j_m, k_m\) not exceeding 2 or 3 \[23\].

Considering now the finite-size susceptibility \(\chi_N(T)\), finite-size scaling \[8\] suggests a form

\[
\chi_N(T) = N^{\gamma/\nu} f_\chi(u), \tag{12}
\]

where \(\gamma\) is the susceptibility exponent. Following Refs. \[25\] and \[26\], we write (again, allowing for corrections to scaling):

\[
\ln \chi_N(T) = \frac{\gamma}{\nu} \ln N + \sum_{j=1}^{j_m} a_j^\chi u^j + N^{-\omega} \sum_{k=0}^{k_m} b_k^\chi u^k. \tag{13}
\]

In order to reduce the number of fitting parameters, it is usual to keep \(1/\nu\) and \(T_c\) fixed at their central estimates obtained, e.g., via Eqs. (11) and (13), allowing \(\gamma/\nu\) to vary.

Expressions similar to Eq. (10) can be written for magnetizations and specific heats, yielding estimates of the exponents \(\beta/\nu\) and \(\alpha/\nu\).

In the present context, one should interpret the exponent \(\omega\) in Eqs. (5), (10), and (13) as an effective one, representing all orders of corrections to scaling (which may also turn out to have rather different amplitudes for different quantities). Thus, in practice a somewhat broad range of results (say, \(1 \lesssim \omega \lesssim 3\)) can be accepted when considering data collapse optimization for distinct quantities related to the same problem.

### III. NUMERICAL RESULTS

#### A. \(H = 0\)

In zero external field, for \(J_2 < 1/2\) the ground-state ordering is of the Néel type, with the two sublattices aligned.
antiparallel to each other; the transition is second-order, in the Ising universality class [12]. At \( J_2 = 1/2 \) the ground state is macroscopically degenerate, and the critical temperature is zero [4]. For \( J_2 > 1/2 \) the lowest energy corresponds to collinear order, with alternating rows (or columns) of parallel spins. For \( J_2 \gtrsim 1/2 \) the transition is first order, and evidence has been found that it remains so, at least up to \( J_2 \approx 0.9 \) [4, 23, 24]. As \( J_2 \) increases further, the second-order character returns. The bulk of extant evidence [24, 27, 28] indicates that it remains so, at least up to \( J_2 \approx 0.9 \) [4, 23, 24]. As \( J_2 \) increases further, the second-order character returns. The bulk of extant evidence [24, 27, 28] indicates that it remains so, at least up to \( J_2 \approx 0.9 \) [4, 23, 24].

For \( J_2 = 1 \), recent estimates of the critical temperature are: \( T_c = 2.0823(17) \) [27], 2.0838(5) [24], 2.0820(4) [3], and 2.0839(12) [24]. By solving Eq. (2), we found a well-behaved sequence of \( T_N^c \) values, extrapolating to \( T_c = 2.08195(5) \) via three-point fits, with \( \omega \approx 3 \). The sequences for \( y_T \) and \( \eta \) from Eqs. (3) and (4) extrapolate respectively to \( y_T = 1.188(2) \) and \( \eta = 0.2341(1) \), again via three-point fits.

Evaluating \( \eta_N(T) \) in the region around \( T_c \), and employing Eqs. (10) and (11), gave \( T_c = 2.08197(5) ; y_T = 1.182(3) \), and \( \eta = 0.2342(1) \), with \( \omega \approx 1.9 \). We used \( j_m = 2 \), \( k_m = 1 \) in Eq. (11). Thus there is a satisfactory degree of consistency between the two methods of evaluation of critical quantities.

Our numerical value for \( \nu = y_T^{-1} = 0.844(4) \) [from averaging over the two results above] is to be compared to \( \nu = 0.8292(24) \) [27]; 0.8481(2) [24]; 0.847(4) [3]; and 0.847(1) [29]. The value \( \eta = 0.20(1) \) was found by direct MC evaluation of critical correlation functions on \( N \times N \) geometries [24].

By evaluating quantities at the extrapolated \( T_c \), we found \( \eta = 0.23415(5) \); as expected, this is even more accurate than extrapolating the sequence of finite-\( N \) values estimated at the respective fixed points \( T_N^c \).

For calculation of the zero-field susceptibility, the specific properties of the collinear order parameter were taken into account as follows. For a fixed coordinate direction, say \( x \), along which the TM proceeds, the critical wavevector is degenerate, being either \( (\pi / a) \hat{x} \) or \( (\pi / a) \hat{y} \), with \( a \) being the lattice parameter. One thus has to take both (equally probable and mutually exclusive) possibilities into account and average the partial contributions given by each. As might be expected, we found both contributions to be of similar amplitudes (within \( \approx 10\% \) of each other for fixed \( N \)); separate fits of each to power-law forms gave apparent exponents differing by less than 1%. The latter discrepancy can be ascribed to residual lattice effects, and is expected to vanish for larger \( N \), out of reach of our TM implementations at present.

Our final result was \( \gamma / \nu = 1.772(1) \). Estimating \( \gamma / \nu \) via Eq. (13) gave \( \gamma / \nu = 1.775(1) \), slightly higher than the previous estimate but within three (rather narrow) error bars. Since the uncertainties quoted refer exclusively to the fitting procedures, i.e., no account is taken of likely systematic errors, one might err on the side of caution and allow for somewhat large uncertainties. Averaging over the two values found, we quote \( \gamma / \nu = 1.773(4) \). This way our results might be considered marginally compatible with \( \gamma / \nu = 1.750(12) \), quoted in Ref. [3], although it seems much harder to stretch our error bars to include the value 7/4, which would be consistent with a weak-universality picture of \( \gamma / \nu = 2 / \alpha / \nu \) sticking to the respective Ising values [30]. Ref. [27] quotes the range 1.71 - 1.79 for \( \gamma / \nu \), based on three different fitting methods.

For the calculation of \( \beta / \nu \), we used as column cumulant in Eq. (7) the following quantity:

\[
\langle M^2 \rangle \approx \frac{1}{2} [\langle M^2 \rangle + \langle M^2 \rangle],
\]

where \( M_u, M_d \) are respectively uniform and staggered column magnetization. This choice reflects the collinear nature of the ground state, with its orientational degeneracy, and closely corresponds to the order parameter used in the MC simulations of Ref. [3]. See the arguments invoked above for the susceptibility calculation. Similarly to the test cases described in Section [11] we found exponent estimates monotonically growing with \( N \); the extrapolated result is \( \beta / \nu = 0.121(2) \), where an \( \alpha \) doubling of the uncertainty found from fits has been incorporated, in order to allow for the small bias shown in tests.

We also evaluated critical specific heats. Finite-size specific-heat sequences can prove unwieldy to extrapolate, even when the exponent \( \alpha \) is positive, as in the case of the two-dimensional three-state Potts ferromagnet [13]. Here, three-point fits of \( N, N - 2, N - 4 \) data gave \( \alpha / \nu \) increasing from \( \approx 0.31 (N = 10) \) to \( \approx 0.33 (N = 20) \), albeit with small oscillations; a quadratic fit of such values against \( 1 / N \) then gave \( \alpha / \nu = 0.351(12) \).

The above results are to be compared to \( \beta / \nu = 0.122(4), \alpha / \nu = 0.357(8) \), both from Ref. [3] and \( \alpha / \nu = 0.412(5) \) [24]. Recalling the Rushbrooke scaling relation, \( \alpha + 2 \beta + 2 \gamma = 2 \), our estimates give \( \alpha / \nu + 2 \beta / \nu + \gamma / \nu = 2.366(13) \), while \( 2 / \nu = 2.370(10) \). Similarly, one has \( (2 - \alpha) / \nu = 2.020(18) \). Given the rather large uncertainties found in the analysis of specific heat behavior, we do not believe that any actual breakdown of hyperscaling is present.

We calculated specific energies at \( T_c \), and fitted them to a quadratic form in \( 1 / N^2 \), thus extracting estimates of the conformal anomaly [8]. From fits of data in the range \( [N_{\min}, 22] \), with \( 4 \leq N_{\min} \leq 14 \), we found estimates of \( c \) decreasing monotonically from \( 1.074(1) \) for \( N_{\min} = 4 \) to \( 1.056(1) \) for \( N_{\min} = 14 \). Uncertainties quoted relate exclusively to the fitting procedure. This range of estimates compares favorably with the corresponding result from Ref. [24] \( c = 1.0613(6) \). It must be kept in mind that what one is seeing most likely amounts to strong crossover effects distorting a picture where \( c = 1 \) [24].

We also considered \( J_2 = 2 \), for which case we obtained, from extrapolating sequences generated via Eqs. (2),
creases [3, 24]. Conformal-anomaly estimates are very
Jc
the ideas behind Eq. (2) do not apply. Indeed, instead of
varying exponents, approaching the Ising ones as
and then became approximately constant for larger
N
scales which are out of reach of our TM calculations, that
is, a weakly first-order transition [4, 24]. Notwith-
sstanding the lack of conceptual justification for using Eq. (2),
it should be noted that Tc ≈ 1.43 is in rather good agree-
ment with MC estimates (see Figure 3 of Ref. 3).

B. H ≠ 0

For J2 = 1, the ground state is still collinear for H < 4,
whereas for 4 < H < 8 it becomes a row-shifted (2 × 2)
state 3. The latter consists of alternating ferro- and
antiferromagnetically ordered rows (or columns), with
the ferromagnetic ones parallel to the field. The added
degree of freedom (relative to a 2 × 2 state) is that the
antiferromagnetic chains can slide freely relative to each
other, at zero energy cost. At H = 4 and 8, Tc = 0
because of macroscopic ground-state degeneracy. The
maximum critical temperature for the transition between
row-shifted (2 × 2) order and the paramagnetic phase has
been estimated as ≈ 0.73, at H ≈ 6 [3].

In order to make contact with previous results, we
initially considered two points on the collinear-
paramagnetic transition line, respectively at H = 2.5 and
3.3 6.

For H = 2.5, from extrapolating sequences generated
via Eqs. (2), (3), and (4), we found Tc = 1.6846(1),
η = 0.2335(1). A noticeable trend reversal was ob-
served for γT; after decreasing from 1.08 to 1.072 be-
tween N = 8 and 12, it starts increasing smoothly, reach-
ing 1.075 at N = 22. Extrapolating N ≥ 12 data, we
found γT = 1.09(4). Evaluating susceptibilities at the
extrapolated Tc resulted in γ/v = 1.779(4), and an-
alysis of magnetizations gave β/ν = 0.122(1). Ref. 3
gives: Tc = 1.6852(3); γT = 1.056(8); γ/v = 1.750(14),
β/ν = 0.118(3). Finally, the conformal anomaly was es-
timated as c = 1.066(1).

Following the same procedure as above, we obtained
for H = 3.3: Tc = 1.3331(5); γT = 0.940(3) (this
time with no trend reversal upon increasing N); η = 0.2338(3). Finite-size susceptibility scaling at Tc gave
γ/v = 1.781(5), and magnetizations, β/ν = 0.135(2).
The evolution of β/ν along the collinear-paramagnetic
phase boundary is analyzed towards the end of this Sec-
Section. Ref. 3 quotes: Tc = 1.3335(6); γT = 0.907(7);
γ/v = 1.751(14), β/ν = 0.130(5). Our estimate for the
conformal anomaly is c = 1.042(1).

The above results show very good numerical agreement
with existing ones as regards critical temperatures; also,
a picture of continuously-varying exponents such as ν and
γ is confirmed, both directly and from the conformal
anomaly results, which are very close to unity. Our values
for γ/v and η do seem consistent with a weak-universality
scenario along the collinear-paramagnetic phase bound-
ary; however, they indicate small but consistent devia-
tions from the Ising-like picture of γ/v = 7/4, η = 1/4.

In order to investigate the latter point in detail, we
proceeded to evaluating η and c along the full extent of
the phase boundary.

We first extrapolated, to N → ∞, the (T, H) values
obtained for sequences of solutions of Eq. (2), with in-
creasing N and either H fixed, or (typically for lower tem-
peratures) T fixed. This was done both for the collinear-
paramagnetic critical line and for that separating the
row-shifted (2 × 2) and paramagnetic phases. In the
former case, we fitted finite-N data with N = 14 – 20
to the single-power form, Eq. (4), finding good conver-
geence with 3 ≤ ω ≤ 4 everywhere on the phase bound-
ary. For the latter, we had extremely slow convergence
of our PRG calculations, which limited us in practice to
N ≤ 16. Probably (at least partially) as a consequence of
this, the single-power form produced rather low ad-
justed values of ω in the neighborhood of 0.5, which
is usually interpreted as indicating strong corrections to
scaling. We thus resorted to ad hoc parabolic fits in N−2,
adjusting N = 10 – 16 data to this latter form.

The behavior in the low-temperature region near H = 4,
where the two distinct phase boundaries become
close to each other, is of special interest since it has
been suggested that an XY-like region might be present
there [4, 5].

In Figure 1 we show our results for the low-temperature
part of the phase diagram, near H = 4. Although nu-
merical convergence difficulties prevented us from reach-
ing T < 0.2 for the largest strip widths, we managed to
evince clearly-defined trends followed along both criti-
cal lines, on their approach to T = 0. Below T = 0.4,
both the collinear-paramagnetic and row-shifted (2 × 2)-
paramagnetic boundaries are, to a very good approxi-
mation, straight, and pointing towards (T, H) = (0, 4) with
respective slopes 0.267(1) and 2.713(5). Concurring
with Ref. 5, it appears very unlikely that an XY-like
region, or a bicritical point at T > 0, is present. In-
stead, all indications from our results are consistent with both critical lines joining at a single bicritical point at $T = 0$. Additionally, we found the maximum of the reentrance on the collinear-paramagnetic phase boundary to be $H = 4.121(2)$ at $T = 0.5$. At $T = 0.7$ we estimate $H = 4.060(6)$. These are in rather good agreement with the respective values $H = 4.07(2)$ and $4.052(7)$, quoted in Ref. 3.

Near $H = 0$, the phase boundary has the expected parabolic shape $T_c(H) = T_c(0) - aH^2$ ($H \to 0$),

$$
T_c(H) = T_c(0) - aH^2 \quad (H \to 0),
$$

where we found $a = 0.0595(3)$ by fitting data corresponding to $0 \leq H \leq 0.4$.

As noted previously in Ref. 11 and above, we generally found finite-size effects to be much larger for the high-field ($4 \leq H \leq 8$) part of the phase diagram. This is illustrated in Figure 2, where finite-$N$ curves with the solutions of Eq. (2) for $N = 10$ and 16 are displayed jointly with our final extrapolation (as described above). At variance with Ref. 3, where $T_c = 0.7293(7)$ is reported at $H = 6$, our extrapolated value is $T_c(H = 6) = 0.589(4)$. Although alternative procedures to our ad hoc parabolic extrapolations against $N^{-2}$ can certainly be devised, it must be noted that for this same field intensity the solution of Eq. (2) is $T_N = 0.706$ already for $N = 10$, and decreases systematically with increasing $N$.

At $(T, H) = (0, 8)$, the initial slope $S = (dH_c/dT)_{T=0}$ of the critical curve gives an estimate of the reduced critical chemical potential $\mu/k_BT_c$ for the hard-square lattice gas with first- and second-neighbor exclusion, via $\mu/k_BT_c = -2S$. Our result for the chemical potential is 5.42, to be compared with 4.70 and 4.91 [34]. This may indicate that our extrapolation procedures slightly underestimate the extent of the row-shifted $(2 \times 2)$ phase.

Figure 2 shows our results for $\eta$ and $c$ along the extrapolated location of the collinear-paramagnetic border, parametrized by $T$. These are obtained from Eqs. (3) and (4), respectively. In part (a), comparison between $N = 10$ estimates and the final $N \to \infty$ extrapolation illustrates that residual finite-size effects contribute towards overestimating the exponent $\eta$, for all $0 < T \lesssim 1.78$ (the approximate point where all finite-$N$ curves cross). On the other hand, for higher $T$ the finite-size corrections change sign. The extrapolated $\eta \times T$ curve is to a large extent horizontal, near both the low- and high-temperature ends of the phase boundary. We estimate $\eta = 0.2476(3)$ for $T \leq 0.5$, and $\eta = 0.2342(3)$ for $T \geq 1.3$. In the intermediate region there is a crossover which becomes rather sharp around $T = 0.8$, at the upper end of the reentrant part of the phase diagram. The conformal-anomaly estimates in part (b) show the same behavior found for $H = 0$ in Section III A, and in Ref. 24, in that they are
always slightly above unity. Similarly to the \( H = 0 \) case, we also found that, upon fitting free-energy data in the range \([N_{\text{min}}, 20]\), the estimates of \( c \) always decrease upon increasing \( N_{\text{min}} \). Thus, an interpretation of the present results as consistent with \( c = 1 \), albeit affected by strong crossover effects, seems credible.

We evaluated critical magnetizations, as given by Eq. (14), along the collinear-paramagnetic phase boundary. Our calculations did not converge for \( T < 0.75 \), which approximately coincides with the reentrant region. Thus, for the part of the critical boundary where we managed to produce estimates of \( \beta/\nu \), there is a one-to-one correspondence between field and temperature. Our results are shown in Figure 4, parametrized by \( H \). This way, it is easier to follow the evolution of quantities for low fields than if we used \( T \) for the horizontal axis, because of the parabolic shape assumed by the critical curve in that region. One sees that the quality of fits generally deteriorates as \( H \) increases; the shallow dip around \( H \approx 1.5 \) is possibly related to slight inaccuracies in the determination of the extrapolated critical line in that region. A more persistent trend is that towards increasing values for larger \( H \). We interpret this as signalling the onset of the physical effects which give rise to reentrant behavior for even larger fields. Indeed, a plausible explanation for the reentrance is, to quote Ref. 3, “the appearance of \((2 \times 2)\) “clusters” that help to sustain the \{collinear\} order at low temperatures even when the external field is slightly bigger than \( 4^\circ \). This sort of cluster is not taken into account in our column-magnetization calculations, see Eq. (14). We also know that the general effect of neglecting relevant contributions to the magnetization is to increase the apparent value of \( \beta/\nu \); for instance, if \( M_a \) is discarded in Eq. (14), the estimate of \( \beta/\nu \) at \( T = 2.0820 \), \( H = 0 \) goes from \( 0.120(2) \) to \( 0.135(2) \). According to this interpretation, for \( H \simeq 2.5 \) or thereabouts, \((2 \times 2)\) configurations which are locally energetically favorable start contributing to ordering in the \( N \rightarrow \infty \) limit, but are not captured in the scheme of Eq. (14). With decreasing \( T \) and increasing \( H \), the effect of such configurations becomes more relevant, providing a mechanism through which the apparent exponent increases, although the real one, we conjecture, possibly increases a little but stays slightly below \( 1/8 \). This would be in line with the behavior of \( \eta \), depicted in part (a) of Figure 3.

Calculation of the thermal exponent \( y_T \) via Eq. (5) in the reentrant region gave negative values, an artifact already noticed in Refs. 10 and 11. However, evaluation of critical finite-size susceptibilities at \( T = 0.35 \) gives \( \gamma/\nu \) in the range \( 1.71 - 1.80 \), depending on the details of corrections to scaling assumed for data fitting. Although lacking in accuracy, this range of values is broadly consistent both with the corresponding \( \eta \) estimate, and with the hypothesis that critical behavior obeys weak universality all along the collinear-paramagnetic critical line.

**Figure 3.** (Color online) (a) Decay-of-correlations exponent \( \eta \) and (b) conformal anomaly \( c \), calculated along the extrapolated collinear-paramagnetic phase boundary. In (a), the dashed line gives estimates of \( \eta \) from strips of width \( N = 10 \) sites, while points are extrapolations from sets of finite-\( N \) estimates, \( N = 14 - 20 \). In (b), values of \( c \) are estimated from quadratic fits of free-energy data against \( N - 2 \) for \( N = 14 - 20 \). Uncertainties are smaller than symbol sizes.

**Figure 4.** (Color online) Finite-size magnetization exponent \( \beta/\nu \) along collinear-paramagnetic (PM) phase boundary. The range of fields, \( 0 \leq H \leq 4.027 \), on the horizontal axis corresponds, respectively, to \( 2.0820 \geq T \geq 0.75 \) (see text). Each point is the result of fitting finite-size data in the range \( 12 \leq N \leq 20 \) to a single-power law, \( \langle M^2 \rangle^{1/2} \sim N^{1-\beta/\nu} \). See Eqs. (6) and (14).
Turning now to the high-field part of the phase diagram, we illustrate in Figure 5 our results for \( \eta \) along the approximate critical lines, the latter obtained by solving Eq. (2) for \( N \) as indicated, for high fields \( 4 \leq H \leq 8 \).

There is also clear evidence that such continuously-varying exponents satisfy, at least approximately, a weak-universality scenario \([30]\). However, as shown for the exponent \( \eta \) in part (a) of Figure 3, our results indicate small but consistent deviations from the corresponding Ising values.

Furthermore, such deviations are internally consistent, in the sense that both \( \eta \) and \( \beta/\nu \) take on values lower than the Ising ones, while \( \gamma/\nu \) is always found to be higher than the Ising result. For \( \beta/\nu \), the apparent reversal of this trend found for \( H \gtrsim 2.5 \) has been explained in Section IIIB as a likely effect of the same sort of locally stable \((2 \times 2)\) configurations which, at lower \( T \) and higher \( H \), become significant enough to induce reentrant behavior.

Notwithstanding the compensation just referred to, our estimates of \((\gamma/\nu) + \eta\) in general exceed 2, though never by more than 2 – 3 times the respective (combined) error bar. However, it must be recalled that here \( \gamma/\nu \) is essentially one order of magnitude larger than \( \eta \), and both quantities have similar relative uncertainties, thus the calculated combined uncertainty is practically only that associated with \( \gamma/\nu \). In such circumstances, the apparent violation of a fundamental scaling relation reflects the fact that the relative uncertainty in \( \gamma/\nu \) was estimated as \( \approx 2 \) parts in \( 10^3 \). Had this been doubled, all the basic conclusions from this work would still stand, and the mismatch would be essentially lost within the revised error bars.

Returning to \( \eta \) as displayed in part (a) of Figure 3, the small but consistent shift between the high- and low-\( T \) approximately constant values \([\text{respectively, } 0.2342(3)\text{ and } 0.2476(3)\text{]}\) indicates a crossover between two distinct weak-universality classes. Such small variations could probably be accounted for in the context of compactified boson theory \([23, 35]\), in which continuously-varying critical indices are put in direct correspondence with the (also continuously-varying) radius \( R \) associated with the underlying field theory.

In general, both for \( H = 0 \) and \( H \neq 0 \) (the latter, along the collinear-paramagnetic critical line) our results for the location of critical points, and exponents such as \( s_T \), \( \gamma/\nu \), and \( \beta/\nu \), are mostly compatible, within error bars, with estimates available in the literature. On the other hand, for the row-shifted \((2 \times 2)\)-paramagnetic phase boundary at high fields, we have found a discrepancy of some 19% between our estimate and that given in Ref. 3, for the highest transition temperature at \( H = 6 \). Even allowing for the (rather plausible) likelihood that our extrapolation procedures underestimate the extent of the ordered phase, for PRG with the largest size available \((N = 16)\) one has \( T_c(H = 6) = 0.651 \), already 11% below \( T_c(H = 6) = 0.7293(7) \) quoted in Ref. 3. At this point, such discrepancy remains unexplained.

We have not succeeded in gathering as much information regarding critical properties of the row-shifted \((2 \times 2)\)-paramagnetic boundary line, as we did for its

\begin{figure*}[h]

\includegraphics[width=0.7\textwidth]{fig5.png}
\caption{(Color online) Decay-of-correlations exponent \( \eta \), evaluated via Eq. (4), along approximate row-shifted \((2 \times 2)\)-paramagnetic transition lines, obtained by solving Eq. (2) for \( N \) as indicated, for high fields \( 4 \leq H \leq 8 \).}
\end{figure*}
collinear-paramagnetic counterpart. However, the behavior of $\eta$ illustrated in Figure 5 reminds one of the low-temperature behavior of the two-dimensional $XY$ model. Indeed, with $T_{KT}$ being the upper limit of the Kosterlitz-Thouless critical phase, the exponent $\eta$ of the $XY$ model grows smoothly and monotonically from $\eta = 0$ at $T = 0$ to $1/4$ at $T_{KT}$ (with most of the increase confined to higher $T$: at $T = 0.5 T_{KT}$, $\eta \approx 0.05$). So the very low values of $\eta$ found in the present case may, or may not, indicate the presence of incipient $XY$-like behavior along at least part of the high-field critical line.
