Thermal dephasing and the echo effect in a confined Bose-Einstein condensate

A. B. Kuklov, and N. Chencinski

Department of Applied Sciences, The College of Staten Island, CUNY, Staten Island, NY 10314

It is shown that thermal fluctuations of the normal component induce dephasing – reversible damping of the low energy collective modes of a confined Bose-Einstein condensate. The dephasing rate is calculated for the isotropic oscillator trap, where Landau damping is expected to be suppressed. This rate is characterized by a steep temperature dependence, and it is weakly amplitude dependent. In the limit of large numbers of bosons forming the condensate, the rate approaches zero. However, for the numbers employed by the JILA group, the calculated value of the rate is close to the experimental one. We suggest that a reversible nature of the damping caused by the thermal dephasing in the isotropic trap can be tested by the echo effect. A reversible nature of Landau damping is also discussed, and a possibility of observing the echo effect in an anisotropic trap is considered as well. The parameters of the echo are calculated in the weak echo limit for the isotropic trap. Results of the numerical simulations of the echo are also presented.

I. INTRODUCTION

Properties of the trapped ultracold atomic gases demonstrating the phenomenon of Bose-Einstein condensation attract much of attention. A confined geometry of the cloud leads to circumstances under which new phenomena such as, e.g., a specific scaling in the thermodynamical properties can be anticipated. It was also suggested that the phase of the confined condensate should demonstrate the phenomenon of collapses and revivals and the phase diffusion effect.

Recently it has been discussed in Refs. [3,4], that the dynamical quantum behavior of the atomic cloud consisting of a finite number of bosons is very different from the properties of infinite systems. Specifically, an amplitude of a normal mode of the confined condensate should demonstrate quantum dephasing which results in an apparent damping of the mode even at zero temperature. The rate of such damping is determined by the interparticle interaction and turns out to be linearly dependent on the mode amplitude, if it is small. A possibility of the mode revival has also been predicted. A current experimental situation does not allow to resolve this effect because of the presence of the normal component which introduces a substantial damping on its own.

Damping of the normal modes at finite $T$ of the confined condensate has been experimentally studied by the JILA [10] and the MIT [11] groups. Recently it was stressed by Pitaevskii [12] (see also in Refs. [13,14]) that the damping in the trap containing condensate is essentially Landau damping (LD) which is collisionless in nature. In other words, it is rather the dephasing of the collective modes than their irreversible dissipation. It is worth noting that the reversible nature of the LD in the classical uniform plasma can be revealed in the plasma echo effect [15].

Theoretical approaches [16,17] are based on applying the standard results of the perturbation theory developed for an infinite and uniform medium. Accordingly, a discrete structure of the quasiparticle spectrum is tacitly replaced by an effective continuum [18]. In the recent work [18] it has been emphasized that the existence of the LD is directly related to a presence of the randomness in the spectrum of the anisotropic traps. Conversely, in the isotropic trap the LD should be suppressed because the quasiparticle spectrum is regular [18].

In this paper, we suggest that in a confined condensate where the LD is suppressed the damping of the collective modes can still be observed. Specifically, thermal fluctuations of the population factors of the normal component induce a reversible dephasing of the collective oscillations. The nature of such a damping is similar to that of the dephasing observed in quantum dots (see in Ref. [19]). We show that, while being essentially zero for a traditional uniform condensate, the rate of such a dephasing $1/\tau_d$ in the trap containing $10^3 - 10^4$ atoms can be comparable to the rate of the damping observed experimentally in Ref. [10].

We also suggest that reversibility of the damping in a confined condensate can be tested in a kind of the phonon echo experiment (see in Ref. [20]), when two consecutive external pulses imposed on the trap induce a third pulse – the echo – at the time approximately equal to twice the time interval between the first two pulses. In this paper we analyze the case of the isotropic trap, where the LD is not expected to be an important mechanism of dissipation. In a future work we will investigate the echo in strongly anisotropic traps, where the main mechanism of damping is the LD.
II. THERMAL FLUCTUATIONS AND DEPHASING IN THE ATOMIC TRAP

In the Refs. [3,4] it has been shown that a collective mode of the confined condensate should exhibit a dephasing caused by the inter-particle interaction. In the case $T = 0$, the dephasing is produced by the particles forming the mode. Below we will consider a similar effect caused by the interaction between a low energy collective mode and the quasiparticles forming a normal cloud.

Let us discuss general reasons for the thermally induced dephasing in the presence of the inter-particle interaction. Especially we will clarify why this effect is not significant for an infinite condensate, where the only cause of the dephasing should be the LD. The following analysis is based on the approach suggested by Pitaevskii in Ref. [3] for the case $T = 0$. We extend this analysis for $T \neq 0$.

If an external modulation at some frequency $\omega_0$ has excited a system, the many body time dependent wave function $|t\rangle$ constructed in terms of the quasiparticle states $|N_0, N_1, \ldots\rangle$ acquires the form

$$|t\rangle = \sum_{N_0, N_1, \ldots} C_{N_0, N_1, \ldots} e^{-iE_{N_0, N_1, \ldots}t} |N_0, N_1, \ldots\rangle,$$

where $N_n$ is a population number for the $n$-th ($n = 0, 1, 2, \ldots$) quasiparticle state; $E_{N_0, N_1, \ldots}$ stands for the energy of the state $|N_0, N_1, \ldots\rangle$ and $C_{N_0, N_1, \ldots}$ denote the normalized coefficients $\langle \sum_{N_0, N_1, \ldots} C_{N_0, N_1, \ldots}^2 = 1 \rangle$. For the case of weak interaction between quasiparticles, the external drive, which is in resonance with the energy of, e.g., the 0-th quasiparticle state, creates a coherent mixture of the quasiparticles in the 0-th state and does not affect significantly the other states. Accordingly, one can factorize $C_{N_0, N_1, \ldots}$ as

$$C_{N_0, N_1, \ldots} = C_{N_0}^{(0)} C_{N_1}^{(1)} C_{N_2}^{(2)} \ldots,$$

and assume that

$$|C_{N_0}^{(0)}|^2 = \frac{N_0 N_0}{N_0!} \exp(-\hat{N}_0),$$

with the rest of the $C$- coefficients corresponding to the number states $(C_{N_n}^{(n)} = 1$ for some $N_n = N'_n$ and $C_{N_n}^{(n)} = 0$ otherwise). In Eq.(3) $\hat{N}_0$ is given by the value of the classical amplitude of the resonant mode [3,4].

The expectation value of the single particle operator $A(t)$, which changes the number of quasiparticles in the given state by 1, acquires a resonant contribution from the 0-th state. This is

$$\langle t | A | t \rangle = \sum_{N_0} C_{N_0}^{(0)*} C_{N_0+1}^{(0)} \hat{A} \exp[i(E_{N_0+1, N_1, \ldots} - E_{N_0, N_1, \ldots})t] + c.c.,$$

where $\hat{A}$ is a corresponding single-particle matrix element. In the case of a weak interaction between quasiparticles, one can expand the energy in accordance with the Landau theory of quantum liquids as

$$E_{N_0, N_1, \ldots} = \sum_n \omega_n N_n + \frac{1}{2} \sum_{mn} g_{mn} N_m N_n + o(N_i N_j N_k),$$

where the coefficients $g_{mn}$ arise due to interaction between quasiparticles.

At finite $T$, the solution (4) should be averaged over the initial values of $N_n$ with $n > 0$, distributed in accordance with a thermal ensemble. Substituting (5) into (4) and neglecting the term $\sim N_0^2$ significant for very small $T$ only (see [3,4]), one obtains

$$\langle t | A | t \rangle_T = \hat{A} e^{i \omega_0 t} \sum_{N_0} C_{N_0+1}^{(0)*} C_{N_0}^{(0)}$$

$$+ (\exp(it \sum g_{0n} N_n))_T + c.c.,$$

with $\langle \ldots \rangle_T$ denoting the thermal average with respect to the population factors $N_n$.

In what follows we will assume that $N_n$ are distributed in accordance with the grand canonical distribution. As will be discussed below, this assumption is valid as long as the mean number of atoms in the condensate $n_c$ is sufficiently large. Thus, after straightforward calculations one finds

$$\langle \exp(it \sum g_{0n} N_n) \rangle_T = \exp\left(-\sum_{n>0} \ln \frac{1 - \exp(i g_{0n} t - \omega_n / T)}{1 - \exp(-\omega_n / T)}\right).$$

We note that in a large system the matrix elements $g_{0n}$ are scaled as $g_{0n} \sim 1/V$ by the effective volume $V$ of the system. Accordingly, in the formal limit $V \to \infty$, one should expand $\exp(i g_{0n} t)$ in Eq.(7) up to the first term $\sim 1/V$ only. Then a smallness of $1/V$ will be compensated by the summation $\sum_n \sim V$. This results in

$$\langle \exp(it \sum g_{0n} N_n) \rangle_T = \exp(it \sum_{n>0} \bar{N}_n),$$

where $\bar{N}_n$ denotes a Bose distribution of the non-interacting quasiparticles. As one can see, in the infinite system fluctuations of the numbers of the quasiparticles do not cause any dephasing. Instead, the frequency $\omega_0$ experiences a thermal shift $\omega_0 \to \omega_0 + \sum_n g_{0n} \bar{N}_n$, and the only cause of the dephasing is the LD.

In the case of a finite system one should keep higher order terms in Eq.(7). As will be shown below, the dephasing rate in the oscillator trap contains a smallness $a/r_{\text{trap}} << 1$, where $a$ and $r_{\text{trap}}$ stand for the
scattering length $\sim 10^{-7} - 10^{-6}$ cm and some typical scale $\sim 10^{-4}$ cm associated with the trapping potential, respectively. Therefore, as long as $a/r_{\text{trap}} \ll 1$, one can neglect the higher terms $o(a^2/r_{\text{trap}}^2)$. Such an approximation corresponds to expanding $\exp(i g_{0n} t) \approx 1 + ig_{0n} t - \frac{g_{0n}^2 t^2}{2} + o(g_{0n}^3)$. This results in Eq. (7) being rewritten as

$$\langle \exp(it \sum_{n>0} g_{0n} N_n) \rangle_T = \exp \left( i \sum_{n>0} g_{0n} \bar{N}_n t - \frac{t^2}{2 \tau_d^2} \right),$$

(9)

where the notation

$$\frac{1}{\tau_d} = \sqrt{\frac{1}{2} \sum_{n>0} g_{0n}^2 \bar{N}_n (1 + \bar{N}_n)}$$

(10)

for the dephasing phase is introduced.

Eqs. (9) and (10) indicate that a collective mode of the confined atomic condensate should exhibit a dephasing induced by thermal fluctuations of the normal component. Below we suggest a model of dephasing of a collective mode of the confined condensate in the Thomas Fermi limit, and calculate the value of $\tau_d$ for the isotropic trap.

III. ADIABATIC EFFECTIVE ACTION FOR THE LOW ENERGY COLLECTIVE MODES

In order to obtain $1/\tau_d$, one should find the coefficients $g_{0n}$ and perform the summation in Eq. (10). An explicit expression for $g_{0n}$ can be derived from a many body Hamiltonian $H$ taken in the standard form

$$H = \int dr \Psi^\dagger (H_1 - \mu) \Psi + H_{\text{int}},$$

$$H_1 = -\frac{\hbar^2}{2m} \Delta + \sum_{i=1,2,3} \frac{1}{2} m \omega_i^2 r_i^2,$$

(11)

$$H_{\text{int}} = \frac{1}{2} u_0 \int dr \Psi^\dagger \Psi^\dagger \Psi \Psi,$$

where the Bose operators $\Psi, \Psi^\dagger$ obey the usual Bose commutation rule; $\mu$ is the chemical potential; $\omega_i$ denote three frequencies characterizing the trapping potential; and the interaction constant $u_0 = 4 \pi \hbar^2 a/m$ is expressed in terms of the scattering length $a$ and the atomic mass $m$. As usual, in the presence of the condensate, one uses the conventional representation

$$\Psi = \Phi_c + \Psi',$$

(12)

where $\Phi_c$ is a classical condensate wave function giving the condensate density $n_c = |\Phi_c|^2$ and normalized to the number $N_c$ of atoms in the condensate; $\Psi'$ stands for the excitation part. For the latter, the Bogolubov representation should be employed as

$$\Psi' = \sum_n (U_n a_n + V_n^* a_n^\dagger),$$

(13)

where $a_n$ destroys a quasiparticle on the level having the energy $E_n$, and $(U_n, V_n)$ is an eigenvector of the linearized Bogolubov equations

$$E_n U_n = H'_1 U_n + u_0 \Phi_c^2 V_n,$$

$$-E_n V_n = H'_1 V_n + u_0 \Phi_c^2 U_n,$$

(14)

$$H'_1 = H_1 + 2 u_0 |\Phi_c|^2 - \mu.$$

Expressed in terms of the quasiparticle operators $a_n, a_n^\dagger$, the Hamiltonian (11) acquires the form

$$H = \sum_n E_n a_n^\dagger a_n + H_{\text{int}},$$

(15)

where the interaction part $H_{\text{int}}$ contains the terms

$$H'_{\text{int}} = \sum_{mnk} (g_{mnk} a_m^\dagger a_n a_k + \text{H.c.}) + \sum_{mnkl} g_{mnkl} a_m^\dagger a_k^\dagger a_l a_\ell,$$

(16)

which could be identified with the terms $\sim N_m N_n$ in Eq. (5). Specifically, performing calculations in the first and in the second orders of the perturbation theory with respect to $H'_{\text{int}}$, one finds the coefficients $g_{kn}$ in Eq. (5) as

$$g_{kn} = 4 g_{kn} + 2 \sum_m |g_{mnk}|^2 \left[ \frac{2(E_n - E_m)}{(E_n - E_m)^2 - E_k^2} - \frac{1}{E_n + E_m - E_k} \right],$$

(17)

where the coefficients $g_{kn}$ and $g_{mn}$ can be expressed explicitly in terms of the Bogolubov amplitudes in Eq. (13) by means of substituting Eq. (12) in Eq. (11) and selecting the terms (16). This yields

$$g_{kn} = \frac{1}{4} \int dr \left[ (|U_k|^2 + |V_k|^2)(|U_n|^2 + |V_n|^2) 

+ (U_k^* V_k^* U_n^* V_n + \text{c.c.}) \right]$$

(18)

and

$$g_{mn} = u_0 \int dr \Phi_c^2 \left[ U_m^* U_n + V_m^* V_n + U_m^* V_n + V_m^* U_n \right]$$

(19)

for real $\Phi_c$.

We note that in the case of a continuum or quasi-continuum spectrum $[13]$, the sum in Eq. (17) gives the main contribution to the imaginary part corresponding to the LD in the lowest order of the perturbation theory $[13, 18]$. In the isotropic trap, this imaginary contribution is not significant $[18]$, which implies that the LD is
suppressed. Therefore, the real value of $g_{kn}$ (17) could be employed in Eq.(10) for calculating $1/\tau_d$. Unfortunately, such an approach leads to an expression $1/\tau_d$ which formally diverges on low energies, despite the natural expectation that the main contribution to the dephasing is produced by high energy excitations. Accordingly, the rate (10) acquires the incorrect $T$-dependence $1/\tau_d \sim \sqrt{T}$ for $\mu > T$. In fact, this divergence can be eliminated by a proper renormalization of the vertex in the low energy region, where an adequate description relies on the hydrodynamical approach [22]. In order to solve this problem for the low energy collective modes, we employ a simple scaling procedure which yields a description of the effect of thermal dephasing in closed form at finite $T$ in the limit of large $N$.

First, we note that the dephasing effect is an adiabatic process when the high energy component follows the evolution of the low energy collective mode without dissipating energy. As was discussed in Ref. [22,23], the low energy confined condensate modes at $T = 0$ can be viewed as time dependent scaling $r_i \rightarrow r_i/b_i$ of the coordinates $r_i$ by some time dependent scaling variables $b_i = b_i(t)$. Furthermore, it has been shown [22] that, if one ignores the kinetic energy term, such a scaling approach is exact for any given initial state of the many body wave function. As will be seen below, this implies that no dephasing of the low energy scaling modes should occur in such an approximation. The dephasing is induced by the kinetic energy terms, which are, however, small in the Thomas-Fermi limit [22]. Such a smallness implies that one can still consider the scaling variables $b_i$ as proper collective degrees of freedom, whose dynamics is modified in the presence of the kinetic terms. Below we will derive an adiabatic classical action for the $b$-variables. In order to do this, we treat the $\Psi$-operator as a classical field by means of considering the $a, a^\dagger$ operators in Eq.(13) as $e$-numbers. Then we employ the scaling ansatz [22]

$$\Psi(r_i, t) \rightarrow e^{i\varphi} \sqrt{b_1b_2b_3} \Psi \left( \frac{r_i}{b_i}, t' (t) \right), \quad \varphi = \frac{m}{2\hbar} \sum_i \frac{\dot{b}_i}{b_i} r_i^2, \quad (20)$$

where $t'(t)$ is some function of time determined in terms of the variables $b_i$ and their time derivatives $\dot{b}_i$. In what follows we assume that the scale invariant shape of $\Psi$ is given by Eqs.(12)-14 obtained for $b_i = 1$. In this manner we eliminate the non-adiabatic processes induced due to $b_i \neq 0$. Consequently, one can derive an effective classical action $S_b = S[\dot{b}_i, b_i]$ for the variables $b_i$ by means of performing the scaling transformation (20) in the full classical action

$$S = \int dt \{ \frac{i}{2} (\Psi^* \dot{\Psi} - h.c.) - H \}. \quad (21)$$

Note that a substitution of the form (12), (13) is to be done in Eq.(11) and, then, in Eq.(21). Then, the off-diagonal products $a_n^* a_m$ and $a_m a_n$ ($m \neq n$) should be eliminated in the adiabatic approximation because these oscillate in time. The diagonal terms $a_n^* a_n$, which do not oscillate, should be retained and identified with the population factors. Let us denote the action obtained as a result of such a procedure as $S_b = \langle S \rangle$. Then, we find

$$S_b = \int dt \{ \sum_i \frac{m}{2} R_i \left( \dot{b}_i^2 - \omega_i^2 b_i^2 \right) - \frac{P_i}{2b_i} - \frac{G}{b_1b_2b_3} \}, \quad (22)$$

where the notations

$$R_i = \int dt \nabla_i \nabla_i \Psi^* \Psi, \quad P_i = \int dt \frac{\hbar^2}{m} \nabla \Psi^* \nabla \Psi, \quad G = \frac{\mu}{2} \int dt \Psi^* \Psi \Psi \Psi$$

are introduced. Taking into account that these quantities do not depend on $b_i$, one can vary $S_b$ with respect to $b_i$ and obtain the classical equations of motion

$$\ddot{b}_i + \omega_i^2 b_i - \frac{G}{mR_i b_i b_1 b_2 b_3} - \frac{P_i}{mR_i b_i^2} = 0, \quad i = 1, 2, 3. \quad (24)$$

We note that these equations reproduce correctly the $T = 0$ low energy spectrum obtained in Ref. [24] for the isotropic trap characterized by the relation $\omega_1 = \omega_2 = \omega_3 = \omega_{ho}$. Indeed, in the case of zero temperature one should take the means (23) over the condensate state by setting $a_n = a_n^* = 0$ in Eq.(13), and, accordingly, taking $\Psi = \Phi_c$ in Eq.(23). Then, the virial theorem yields

$$m\omega_i^2 R_i^{(c)} - P_i^{(c)} - G^{(c)} = 0, \quad (25)$$

with the superscript $(c)$ indicating that the means in Eq.(23) are taken over the condensate state. Employing this relation in Eqs.(24), one finds

$$\ddot{b}_i + \omega_i^2 b_i - \omega_i^2 (1 - \xi_i^{(c)}) \frac{1}{b_i b_1 b_2 b_3} - \xi_i^{(c)} \omega_i^2 \frac{1}{b_i^2} = 0, \quad (26)$$

where the notation

$$\xi_i^{(c)} = \frac{P_i^{(c)}}{m\omega_i^2 R_i^{(c)}} \quad (27)$$

is introduced. We note that $\xi_i^{(c)}$ determines the ratio of the averages of the kinetic energy to the harmonic potential energy both taken for the $i$-direction. Accordingly, for the case of the isotropic trap considered in Ref. [24] one can find $\xi_i^{(c)} = E_{kin}/E_{ho}$, where $E_{kin}, E_{ho}$ stand for the total kinetic and the total harmonic energies, respectively. Then, from the linearized version of Eqs.(26) we reproduce the frequencies of the quadrupolar mode $\omega_Q = \sqrt{2\omega_{ho}(1 + E_{kin}/E_{ho})^{1/2}}$ and of the breathing mode $\omega_M = \omega_{ho}(5 - E_{kin}/E_{ho})^{1/2}$ derived in Ref. [24].

Note also that for $T \neq 0$, Eqs.(24) coincide with those derived in Refs. [22,23] in the Thomas-Fermi limit. This can be seen by means of setting the kinetic energy terms
\( P_i = 0 \) in Eqs. (24) and performing the scaling transformation

\[ b_i = \kappa_i \tilde{b}_i \]  

(28)

with some \( \kappa_i \) chosen in such a way as to make the solution \( \tilde{b}_i = 1 \) to be the equilibrium one. Furthermore, it can be seen that in the isotropic 2D case, when only two scaling variables \( b_1 \), \( b_2 \) should be taken into account, the dependence on \( P_i \) can be eliminated by the scaling transformation (28), so that the frequency of the breathing mode does not depend on \( P_i \). This implies that no dephasing of the 2D breathing mode should occur in accordance with the result of exact calculations of Ref. [25].

In order to simplify the following analysis of the \( T \neq 0 \) case, let us consider a breathing mode in the 3D isotropic trap. Thus, we set \( b = b_1 = b_2 = b_3 \) and \( b = \kappa \tilde{b} \) in the transformation (20) as well as in the action \( S_b \) (21). Then, varying \( \delta S_b / \delta \tilde{b} = 0 \), we obtain the nonlinear equation describing the low energy adiabatic dynamics of the breathing mode in the presence of the normal component:

\[ \frac{\ddot{b}}{\omega_{h0}^2} - \frac{\omega_{h0}^2}{b^3} + \xi \omega_{h0}^2 \frac{1 - \tilde{b}}{b^4} = 0, \quad \xi = \frac{P}{mR\omega_{h0}^2 \kappa^4}, \]  

(29)

where \( P = P_1 + P_2 + P_3, \quad R = R_1 + R_2 + R_3 \) and \( \kappa \) obeys the relation

\[ \omega_{h0}^2 = \frac{P}{m\kappa^3 R} - \frac{3G}{m \kappa^3 R} = 0. \]  

(30)

An explicit form of \( \xi \) can be found in the limit \( P \to 0 \), which corresponds to neglecting the kinetic energy of the system if compared with the interaction energy. Setting \( P = 0 \) in Eq. (30), one finds \( \kappa \) and then, resorting back to Eq. (29), obtains

\[ \xi = \frac{P}{\omega_{h0}^{2/5} (mR)^{1/5} (3G)^{4/5}}. \]  

(31)

In order to express \( P, R, G \) in terms of the products \( a^*_m a_n \) which, as was mentioned above, should be identified with the population factors \( N_n = a^*_m a_n \) of the quasiparticles in the second quantized picture, one should use the representations (12), (13), (23). However, in the Thomas Fermi limit valid for large numbers \( N_c \) of atoms in the condensate, one may neglect corrections to \( R, G \) and \( N_c \) due to the excitations at not very large temperatures. Indeed, in the condensate state \( R \sim G \sim N_c r_c^2 \), where \( r_c \) stands for the condensate radius \( r_c \sim N_c^{2/5} \) [20]. Therefore, \( R \sim G \sim N_c^{7/5} \). The kinetic term \( P \sim N_c / r_c^2 \sim N_c^{3/5} \). High energy excitations produce changes \( \delta R, \delta G, \delta N_c, \delta P \) of \( R, G, N_c, P \), respectively. Therefore, their relative contributions \( \delta R / R, \delta G / G, \delta N_c / N_c \) and \( \delta P / P \) to the value of \( \xi \) are very different. Specifically, the first two terms contain an additional smallness \( \sim N_c^{-4/5} \) if compared with the last one. Therefore, in calculating \( \xi \) in Eq. (31), one should take into account only the contribution due to \( \delta P \), and take the values \( R, G \) determined for the condensate state by Eq. (23) for some mean value of \( N_c \).

The term \( \delta N_c / N_c \), arising due to the conservation of the total number of particles, can be neglected as well. Indeed, if the normal component fluctuates by some number \( \delta N' \), the conservation of the total number implies that \( \delta N_c = -\delta N' \). The kinetic term fluctuates as \( \delta P \sim \delta N' \). Therefore, the ratio \( \delta N_c / N_c \) over \( \delta P / P \) contains a smallness \( \sim N_c^{-2/5} \ll 1 \).

Finally, employing representations (12), (13) in (23) and taking the means so that \( \langle a^*_m a_n \rangle = N_n \delta_{mn} \), one finds

\[ \xi = \xi^{(c)} + \sum_n g_n N_n, \]

\[ g_n = -\frac{\hbar^2}{m^2 R_c \omega_{h0}^2} \int d\Omega U_n^* \Delta U_n + V_n^* \Delta U_n, \]  

(32)

\[ R_c = \int d\Omega^2 |\Phi_c|^2, \]

where the virial relation (25) has been utilized, and \( \xi^{(c)} \) denotes the contribution due to the kinetic energy of the condensate. In what follows we will neglect this term which does not depend on \( N_n \).

The solution \( \tilde{b} \) of Eq. (29) should be averaged over \( \xi \) represented by Eq. (32). Such an averaging can be understood as a thermal ensemble averaging over possible Fock states of the quasiparticles. This interpretation closely resembles the case of destructive measurements [14], when the initial conditions determined by \( N_n \) for each newly created condensate can vary from one condensate to another. In the case of non-destructive measurements, the averaging of the solution \( \tilde{b} \) should be performed over a single many body state, which is a mixed state rather than a pure Fock state with respect to \( N_n \). In accordance with the ergodic hypothesis such an averaging should give the same result as that obtained by means of thermal averaging as long as the number of quasiparticles is sufficiently large. In what follows we will not distinguish these two cases, and will employ the thermal averaging \( \langle \ldots \rangle_T \) with respect to \( N_n \). This averaging can be performed explicitly for the linearized solution of Eq. (29). Specifically, representing \( \tilde{b} = 1 + \eta \) in Eq. (29) and keeping the terms linear in \( \eta \), one finds

\[ \langle \eta(t) \rangle_T = \eta_0 e^{\omega_{h0} (5 - \xi) t^{1/2}} + c.c. \sim \]

\[ e^{\omega_M t - t^2 / \tau_M^2} + c.c., \]  

(33)

\[ \omega_M = \sqrt{5\omega_{h0} - \frac{1}{2\sqrt{\xi}}} \langle \xi \rangle_T. \]

where \( \eta_0 = const \) accounts for the initial condition \( \tilde{b}(0) = 1 + \eta_0 \), and the dephasing rate of the breathing mode is
we find

\[
\frac{1}{\tau_{dM}} = \omega_{ho} \sqrt{\frac{1}{20} \sum_n g_n^2 \bar{N}_n (1 + \bar{N}_n)},
\]

(34)

with the coefficients \(g_n\) given by Eq.(32). Performing similar calculations for the quadrupolar mode, we find the relation \(1/\tau_{dQ} = \sqrt{5/2}/\tau_{dM}\) for the dephasing rate of the quadrupolar mode. Taking into account Eqs.(32), (34), we obtain an explicit expression for the rate \(1/\tau_{dM}\)

(34) in the WKB approximation [27] (see Appendix A) as

\[
\frac{1}{\tau_{dM}} = \Gamma_M D(T/2\mu),
\]

(35)

where the coefficient \(\Gamma_M\) is

\[
\Gamma_M = \frac{35}{\sqrt{3}} \left( \frac{r_{ho}}{r_c} \right)^2 \frac{a}{r_{ho} \omega_{ho}}, \quad r_{ho} = \sqrt{\frac{\hbar}{m \omega_{ho}}},
\]

(36)

and the universal dimensionless function \(D(\beta)\) is defined in Appendix A (see Fig.1), with the parameters \(r_c, \mu\) given explicitly in (A2).

In the limits \(\beta \gg 1\) \((T >> 2\mu)\) and \(\beta << 1\) \((T << 2\mu)\) the function \(D(\beta)\) can be found explicitly (see Eqs. (A28) and (A32), respectively). The current experimental situation is closer to the first case. It is convenient to express \(T\) in units of the transition temperature \(T_c\) of the Bose-Einstein condensation in the isotropic oscillator trap

\[
T_c = \rho_{ho} \left( \frac{N}{\zeta(3)} \right)^{1/3},
\]

(37)

where \(\zeta(3) \approx 1.202\); \(N\) is the total number of the trapped atoms (for \(T\) not very close to \(T_c\) we set \(N_c \approx N\)). Then, we find

\[
\frac{1}{\tau_{dM}} = \frac{35 \sqrt{3}}{15^{7/5}(\zeta(3))^{5/6}} \left( \frac{T}{T_c} \right)^{5/2} \left( \frac{r_{ho}}{a} \right)^{2/5} N^{-17/30} \omega_{ho}
\]

(38)

from Eqs.(35)-(37), (A28), (A29). Choosing the values \(T/T_c = 0.9\), \(N = 2 \times 10^3 - 10^4\) and \(\omega_{ho} = 2\pi \times 200\) s\(^{-1}\), \(r_{ho} = 10^{-4}\) cm typical for the experiment [10], we obtain the rate \(1/\tau_{dM} \approx 40\) s\(^{-1}\) - 20 s\(^{-1}\). We note that these values of \(1/\tau_{dM}\) are close to the damping rate observed in Ref. [10]. However, for the chosen parameters, \(\beta = T/2\mu \approx 1.3\) which is far from the requirement \(\beta \gg 1\) insuring the validity of Eq.(38). Nevertheless, the above estimates remain valid. Indeed, evaluating the complete expressions (A18), (A19) numerically (see Fig.1) changes these estimates by only about 20%. Specifically, the rate becomes \(\approx 50\) s\(^{-1}\) - 25 s\(^{-1}\). For the lowest temperature achieved in the experiment [10] \(T \approx 0.4 T_c\), Eq.(38) becomes invalid because this temperature corresponds to \(\beta \approx 0.6 < 1\).

Accordingly, a numerical evaluation of \(D(\beta)\) by means of Eqs. (A18), (A19) and, then, a substitution of the result into Eq.(35) yields the rate \(1/\tau_{dM} = 8 s^{-1} - 4 s^{-1}\) which is also in the range obtained by the JILA group [10].

We emphasize that in the anisotropic trap employed by the JILA group the damping is most likely to be caused by the LD [12, 13, 14], and not by the mechanism discussed above. The discussed mechanism in its pure form can be realised in the isotropic trap only. Therefore, a correspondence between the rate calculated above for the isotropic trap and that measured by the JILA group [10] for the anisotropic trap indicates that, while decreasing a degree of the trap anisotropy, the damping rate should practically stay unchanged despite the fact that the nature of the damping changes.

In the case \(T \ll 2\mu\) one could use an explicit form (A32) for \(D(\beta)\) and, correspondingly, find an explicit \(T\)-dependence of the rate (35). However, in this case the rate becomes so small, that the mechanism of the quantum self-dephasing [10] comes into play.

It is interesting to investigate the dependence of the dephasing rate on the amplitude of the oscillations. It is worth noting that in the case \(T = 0\) such a dependence is very pronounced [10]. In contrast, as will be seen below, the amplitude dependence at finite \(T\) is weak. Indeed, this dependence is due to the nonlinearity of the term \(\sim \xi\) in Eq.(29). In the lowest order with respect to the initial value \(\eta_0\) in Eq.(33), this dependence can be obtained by expanding Eq.(29) up to the terms \(\sim \eta^2\) and \(\eta^3\) and finding the correction to the frequency of the lowest harmonic in the order \(\sim |\eta_0|^2\). Performing straightforward calculations (see Appendix B) and then averaging over the ensemble, we obtain

\[
\frac{\tau_{dM}}{\tau_{dM}(A)} = 1 - \frac{7}{3} |A_1|^2
\]

(39)
the ratio of the rate $1/\tau_{\text{coll}}(A_1)$ determined in the second order with respect to the amplitude $A_1 = 2\eta_0$ of the collective mode to the rate $1/\tau_{\text{coll}}$ in the 0-th order given by Eqs. (34), (35). As one can see, the rate demonstrates a slow decrease as a function of the amplitude $A_1 < < 1$.

Here we have shown that the collective excitations of the confined Bose-Einstein condensate should demonstrate a dephasing caused by thermal fluctuations of the normal component. In the following section we will discuss how this dephasing effect can be distinguished from irreversible dissipation experimentally.

IV. THE ECHO EFFECT IN A CONFINED BOSE-EINSTEIN CONDENSATE

The reversible nature of the damping can be tested in an echo experiment similar to the spin echo, the photon echo and the phonon echo effects (see in Ref. [24]). The nature of this effect can be briefly outlined as follows [28]. A short external pulse imposed on the system at the time $t = 0$ excites a collective mode. The collective mode amplitude decays due to dephasing as well as due to irreversible dissipation. Both processes are characterized by their typical rates $1/\tau_d$ and $\gamma$, respectively. The second pulse imposed at the time $t = \tau$ partly reverses in time the evolution of the system initiated by the first pulse. This implies a partial revival of the dephased amplitude at the time $t \approx 2\tau$. We note that the occurrence of the echo is a general property of the system where irreversible damping is weaker than the dephasing. Thus, a necessary condition for observing a distinct echo is $\tau_d < 1/\gamma$, $\tau < \tau < 1/\gamma$.

Specific features of the echo depend on the details of the system. The time profiles of the responses, as Eq.(33) indicates, should be gaussian in the case of the thermal dephasing discussed above. In the case of the LD these responses should be characterized by exponential relaxing. Presently available experimental data [24,25] do not allow the distinguishing of the gaussian type damping from the exponential one [26]. In the next paper we will analyze the echo in the anisotropic confined condensate, where the main cause of the damping is the LD. Below we will study the situation in the isotropic trap, where the dephasing is caused by the thermal mechanism described in Sec.III.

A relevant description for the case under consideration relies on Eq.(29) modified to incorporate the external drive as well as some possible irreversible dissipation. As was discussed in Ref. [22], the external drive $\delta \omega^2(t)$, which changes the curvature of the trapping potential, should be included in the linear part of the equation for the scaling variable $\tilde{b}$. Accordingly, Eq.(29) is rewritten as

$$\tilde{b} + \left[\omega_{\text{ho}}^2 + \delta \omega^2(t)\right] \tilde{b} - \frac{\omega_{\text{ho}}^2}{b_4} + 2\gamma \tilde{b} + \xi \omega_{\text{ho}}^2 \frac{1 - \tilde{b}}{b_4} = 0. \tag{40}$$

For $\xi = \gamma = 0$, one obtains the equation derived in Refs. [22,23] for the case $T = 0$. The term $\sim \gamma$ describes the irreversible dissipation at $T \neq 0$. The term $\sim \xi$ introduced already in Eq.(29), with $\xi$ given by Eq.(32), accounts for the dephasing effect discussed above.

The time dependent part $\delta \omega^2(t)$ of the frequency should be driven so as to be in resonance with the collective mode, that is in the form

$$\delta \omega^2(t) = -f(t)\exp(i\omega_0 t) - f^*(t)\exp(-i\omega_0 t), \tag{41}$$

where $\omega_0 = \sqrt{\delta \omega_{\text{ho}}}$ and $f(t)$ stands for the complex amplitude of the external drive. In order to avoid exciting other modes of the system, this amplitude should be considered as a slow envelope of the resonant drive with a typical time $\tau_f >> \omega_0^{-1}$. The echo, then, can be produced by making $f(t)$ reach a maximum at $t = 0$ and then become zero until the time $t = \tau$, when $f(t)$ peaks again. For sake of simplicity, we will ignore other modes and will analyze the simplest situation when the external drive produces two $\delta$-pulses

$$\delta \omega^2(t) = -f_1\delta(t) - f_2\delta(t - \tau) \tag{42}$$

at $t = 0$ and $t = \tau$ having amplitudes $f_1, f_2$, respectively.

For the case of small amplitudes $f_1, f_2$ of the drive, one should look for an evolution of the small perturbation around the equilibrium value $\tilde{b} = 1$. We note that, in contrast with the conventional situation [20], the echo response in our model does not require non-linearity of the dynamical equation. This is due to the fact that the external drive plays a two-fold role. Specifically, on one hand, it gives rise to an effective external force $-\delta \omega^2(t)$ and, on the other hand, excites the system parametrically. Indeed, linearizing Eq.(40) by the substitute $\tilde{b} = 1 + \eta$, with $\eta << 1$, one obtains

$$\eta + [\omega_{\text{ho}}^2(5 - \xi) + \delta \omega^2(t)]\eta + 2\gamma \eta = -\delta \omega^2(t), \tag{43}$$

where the higher order terms of $\eta$ are neglected.

We assume that initially at $t = -\infty$ the mode was not excited ($\eta(-\infty) = \eta(-\infty) = 0$). Then taking into account Eq.(42), one finds form Eq.(43)

$$\eta(0) = 0, \quad \eta(0) = f_1 \tag{44}$$

after the first pulse. The second pulse at $t = \tau$ results in a jump of $\eta$ so that

$$\eta(\tau + \varepsilon) = \eta(\tau - \varepsilon) + f_2(1 + \eta(\tau)), \quad \eta(\tau + \varepsilon) = \eta(\tau - \varepsilon) = \eta(\tau), \tag{45}$$

where $\varepsilon \rightarrow 0$.

We are looking for a solution at $t > \tau$. It has the form

$$\eta(t) = A e^{iQ(\tau - t)} + A^* e^{-iQ(\tau - t)} , \quad Q = \omega_0(5 - \xi)^{1/2} \approx \sqrt{\delta \omega_{\text{ho}}} (1 - \frac{\xi}{10}) , \tag{46}$$

where we have taken into account that $\gamma << \omega_{\text{ho}}$ and $\xi << \omega_{\text{ho}}$. An explicit expression for the coefficient $A$
can be obtained if one employs the conditions (44), (45). Finally, we find the solution (46) for \( t > \tau \) expressed as

\[
\eta(t) = \frac{f_1}{2\gamma f_0}(1 + \frac{f_2}{2\gamma f_0})e^{iQ(t-\gamma)t} + \frac{f_2}{2\gamma f_0}e^{iQ(t-\gamma)(t-\tau)} + \eta_e(t) + c.c. \tag{47}
\]

where

\[
\eta_e(t) = \frac{f_2 f_1}{4Q^2}e^{iQ(t-2\tau)-\gamma t} \tag{48}
\]

represents the echo occurring at the time moment \( t = 2\tau \). Indeed, after thermal averaging over \( N_n \), one finds

\[
\langle \eta(t) \rangle_T = \frac{f_1}{\omega_0} [\sin(\omega t) - \frac{f_2}{2\omega_0} \cos(\omega t)]e^{-\gamma t - t^2/\gamma^2_{\xi} + \frac{2f_2}{\omega_0} \sin(\omega(t-\tau))e^{-\gamma(t-\tau) - (t-\tau)^2/\gamma^2_{\xi}} + \frac{f_2 f_1}{10\omega_0^2} \cos(\omega(t-2\tau))e^{-\gamma t - (t-2\tau)^2/\gamma^2_{\xi}}. \tag{49}
\]

The echo amplitude can be defined as \( A_e = \langle \eta(2\tau) \rangle_T \) in the case when the last term in Eq.(49) dominates the sum. In this case we find

\[
A_e = \frac{f_2 f_1}{10\omega_0^2} e^{-2\gamma t}. \tag{50}
\]

In deriving Eqs.(49), (50) in the limit under consideration, we have made the replacement \( Q = \sqrt{3}\omega_0 \) everywhere in Eqs.(47), (48) except in the exponents, where \( Q \) linearized in \( \xi \) and given by Eq.(46) has been employed. Thus, we obtained the echo effect in the linear approximation.

We have also analyzed the non-linear echo problem for Eq.(40) numerically. This equation was solved for a given value of \( \xi \), and then the final solution was averaged over the values of \( \xi \) distributed in accordance with the gaussian \( G(\xi) = \theta/\sqrt{\pi} \exp(-\xi^2/\theta^2) \), where \( \theta \) determines the effective width of the distribution in such a way that the averaging of the linearized solution reproduces the result (33), (34). Specifically, we set \( \theta = \sqrt{80}/\omega_0^2dM \). The results of the calculations are shown in Fig.2. In the case a) the amplitude of the second pulse is too small to make the echo observable. In the case b) the second amplitude is 5 times stronger so that the echo is distinct. In the case c), while the second pulse amplitude \( f_2 \) is the same as in the cases a) and b), the amplitude of the first pulse \( f_1 \) is two times larger than that in the cases a),b) (note the different scale of the vertical axis in the case c)). As one can see, the echo in this case merges with the tail of the second pulse, which creates an impression that the decay time of the second pulse increases by several times. In order to produce the echo in the case of the large amplitudes \( f_1, f_2 \), the time separation \( \tau \) between the pulses should be increased. However, in this case the irreversible dissipation may strongly suppress the echo in accordance with Eq.(50).

The echo effect analyzed above is a classical mechanics effect. Below certain temperature \( T_Q \), the rate of the quantum dephasing \( \frac{\gamma_{\tau\tau}}{T} \) should become faster than the damping induced by the normal component. Accordingly, the classical treatment employed above becomes no longer valid. The problem should be reformulated in terms of the quantum dynamics of the variable \( \eta \) in a sense of the approach \( \hat{\eta} \), with the external drive (42) taken into account. It can be shown that the echo still exists at \( t = 2\tau \). Therefore, the spontaneous quantum revival, determined by the interaction constant and thereby occurring at very long times \( \hat{\eta} \), can be induced to occur at much shorter times comparable with the time of the quantum collapse \( \hat{\eta} \). This problem will be considered in a separate publication.

V. DISCUSSION

We have suggested a mechanism for the apparent damping of a Bose-Einstein condensate confined in the isotropic oscillator trapping potential. This damping is a reversible dephasing of the collective modes caused by thermal fluctuations of the population factors of the normal component. The calculation of the dephasing rate gives a value which is comparable with the experimentally observed rate of the damping of the low energy collective modes in the atomic traps.

This mechanism of dephasing relies on the ensemble averaging of the collective mode over the initial population of the normal component. Thus, an assumption is
made that for any given initial distribution of the population factors of the “hot” quasiparticles, this distribution does not relax to equilibrium during the time of the dephasing \( \tau_d \). Accordingly, processes of relaxation due to the LD or collisions may suppress the discussed mechanism, if their relaxation times are comparable with \( \tau_d \). As long as the collisional damping introducing irreversibility is unlikely to be relevant for such small temperatures and densities, the LD is the only competing mechanism. However, the LD is expected to be significant for substantially anisotropic traps only [15]. Therefore, in the traps characterized by small anisotropy our mechanism should dominate.

Both mechanisms of damping – Landau damping and that considered above – are reversible in nature, and therefore the evolution of the system can be partly reversed in time. We suggest testing this in the atomic traps by employing the echo effect. As our analytical and numerical calculations for the breathing mode in the isotropic trap indicate, the echo amplitude as well as its position depend on the parameters of the external drive which can be varied over a wide range.

ACKNOWLEDGMENTS

The authors greatly appreciate very useful discussions with Lev Pitaevskii, Eric Cornell and Joseph Birman. We also thank Alfred Levine and William Schreiber for stimulating conversations related to this work. This work was supported by the PSC-CUNY Research Award Program.

APPENDIX A: WKB CALCULATION OF THE DEPHASING RATE

The WKB calculation of the dephasing rate presented here is essentially based on the results of Ref. [27]. Employing Eqs. (14) as well as the normalization condition

\[
\int dr (|U_n|^2 - |V_n|^2) = 1
\]

in Eq. (32), one finds

\[
g_n = \frac{2}{mRc\omega_n^2} \left\{ E_n - \int dr \left[ \left( \frac{m\omega_n^2 r^2}{2} + 2|K|^2 - \mu \right)(|U_n|^2 + |V_n|^2) + (KV_nU_n^* + \text{c.c.}) \right] \right\},
\]

where the notation \( K = u_c\Phi_c^2 \) is introduced, and for the condensate wave function \( \Phi_c = \sqrt{n_c} \) we employ the Thomas Fermi solution [28]

\[
n_c = \frac{m\omega_n^2}{2\hbar^2} \left( \frac{r^2}{c} - r \right) \Theta(c - r),
\]

\[
r_c = \frac{\hbar}{m\omega_n^2}, \quad \mu = \frac{m\omega_n^2 r^2}{2},
\]

were \( \Theta(z) \) is the step function; \( u_c \) and \( r_{ho} \) are defined in Eq. (11) and Eq. (36), respectively. Accordingly, one finds the value of \( R_c \) in Eq. (32) as

\[
R_c = \frac{r_c^7}{35\pi r_{ho}^5}.
\]

States in the isotropic trap can be classified in terms of the angular momentum \( L \), its \( z \)-component \( L_z \) and the radial quantum number \( n_r \). Thus, the index in (A1) as well as in the sum (34) should be understood as consisting of these three quantum numbers. This implies that the summation \( \sum_n \ldots \) in Eq. (34) runs over three quantum numbers \( n = (n_r, L, L_z) \). Because of the spherical symmetry, the summation over \( L_z \) can be performed trivially, which gives \( \sum_{n_z} \ldots = \sum_{n_r} \sum_L (2L + 1) \). As will be seen below, the large values \( n_r \gg 1 \), \( L \gg 1 \) dominate this sum. Therefore, we replace the summation by the integration over \( n_r, L \)

\[
\sum_n \ldots \approx \int_0^\infty dn_r \int_0^{L_0} dL 2L \ldots,
\]

where the upper limit \( L_0 \) is to be determined, and we made the replacement \( 2L + 1 \approx 2L \). It is convenient to change the variable \( n_r \) to \( E \) by employing the quantization condition [27]

\[
n_r + \frac{1}{2} = \frac{1}{\pi \hbar} \int_{r_1}^{r_2} dr_p,
\]

\[
p_r = \sqrt{2m(\sqrt{E^2 + |K|^2} - U_{eff}(r))},
\]

where

\[
U_{eff}(r) = \frac{1}{2} m\omega_n^2 r^2 \left( \frac{\hbar^2 (L + 1/2)^2}{2mr^2} + 2|K| - \mu \right)
\]

denotes the effective WKB potential [27], and the turning points \( r_1, r_2 \) obey the equation \( p_r = 0 \) or

\[
\sqrt{E^2 + K^2} - U_{eff}(r) = 0.
\]

Then the integral (A4) acquires the form

\[
\frac{2}{\pi \hbar} \int_0^\infty dE \int_0^{L_0} dL \int_{r_1}^{r_2} \frac{dr}{v_r},
\]

where Eq. (A5) has been employed, and \( v_r \) stands for the WKB radial velocity [27].

Before we proceed, it is convenient to employ dimensionless variables of length, energy and angular momentum as

\[
x = \frac{r}{r_c}, \quad \epsilon = \frac{E}{\hbar \omega_n r_c^2}, \quad J = \frac{L^2}{r_c^2}
\]

respectively. Note that in these units the condensate radius \( r_c \) equals 1, and the chemical potential \( \mu \) and the quantity \( K \) become
\[
\mu' = \frac{\mu \epsilon_0^2}{\hbar \omega_{\phi}} = \frac{1}{2} \quad k = \frac{1}{2}(1 - x^2) \Theta(1 - x), \quad (A10)
\]
respectively. Accordingly, Eq. (A7) yields two sets of solutions for the dimensionless turning points \(x_{1,2} = r_{1,2}/r_c\)
\[
x_1 = \sqrt{y_0}, \quad x_2 = \sqrt{b_+}, \quad J < \sqrt{2\epsilon} \quad (A11)
\]
where
\[
y_0 = \frac{J^2(1 + \sqrt{1 + 4\epsilon^2 + 2J^2})}{4\epsilon^2 + 2J^2}, \quad (A12)
\]
and
\[
b_\pm = \epsilon + \frac{1}{2} \pm \sqrt{(\epsilon + \frac{1}{2})^2 - J^2},
\]
\[
x_1 = \sqrt{y_0}, \quad x_2 = \sqrt{b_+}, \quad \sqrt{2\epsilon} < J < \epsilon + \frac{1}{2}, \epsilon > \frac{1}{2}, \quad (A13)
\]
As has been discussed in Ref. [27], the solutions (A11) and (A13) correspond to the case when the classically allowed region extends into the condensate and to the case when it is totally outside the condensate, respectively. The \(U, V\)-amplitudes inside the classically allowed region are [27]
\[
U = \frac{C_0(\epsilon, J)}{2r_c^{3/2}} (S_+ + S_-) \frac{\sin \phi}{x^{1/2}v_x} Y_{L,L_z}, \quad (A14)
\]
\[
V = \frac{C_0(\epsilon, J)}{2r_c^{3/2}} (S_+ - S_-) \frac{\sin \phi}{x^{1/2}v_x} Y_{L,L_z},
\]
Here \(S_k = \sqrt{1 + (k/\epsilon)^2} \pm (k/\epsilon)\); \(Y_{L,L_z}\) is the spherical harmonic; the normalization constant is
\[
C_{-2}^0(\epsilon, J) = \frac{1}{2} \int_{x_1}^{x_2} \frac{dx}{v_x}, \quad (A15)
\]
and the dimensionless radial velocity \(v_x = \frac{\sqrt{m r_c}}{\hbar \omega_{\phi}} \frac{r}{r_c^2} v_r\) is given by
\[
v_x = \sqrt{\frac{2\epsilon^2 + k^2}{\epsilon^2} (\sqrt{\epsilon^2 + k^2} - k - \frac{J^2}{2\epsilon^2})}, \quad (A16)
\]
inside the condensate and by
\[
v_x = \sqrt{2\epsilon + 1 - x^2 - J^2/\epsilon^2}, \quad 1 < x < x_2 \quad (A17)
\]
outside the condensate. In calculation of \(C_0(\epsilon, J)\) and in what follows, we replace \(\sin^2 \phi\) by \(1/2\) because the WKB phase \(\phi\) [27] varies rapidly inside the classically allowed region. The integrals outside this region are exponentially small, and we neglect them.
Substituting (A14) into (A1) and employing the units (A9) in Eq. (34), we find the expressions (35), (36) where the dimensionless function \(D(\beta)\) is defined as
\[
D(\beta) = \left[ \int_0^{\infty} \frac{dx}{(e^{x/\beta} - 1)^2} \rho(\epsilon) \right]^{1/2}, \quad (A18)
\]
with the notation
\[
\rho(\epsilon) = \int_0^{J_0(\epsilon)} dJ \frac{C_0^2(\epsilon, J)}{2} \left( \int_{x_1}^{x_2} \frac{dx}{v_x} \right)^{-1}
\]
\[
(\frac{1}{2} - 1 + 2k) \sqrt{1 + \frac{k^2}{\epsilon^2} + \frac{k^2}{\epsilon}}
\]
introduced, and \(k\) determined in Eq. (A10). The value of the limit \(J_0(\epsilon)\) can be found from Eqs. (A11), (A13). Specifically, for \(\epsilon \leq 1/2\), only the case (A11) can be realized. This implies that
\[
J_0(\epsilon) = \sqrt{2\epsilon}, \quad \epsilon \leq \frac{1}{2}. \quad (A20)
\]
For \(\epsilon > 1/2\), Eq. (A13) yields
\[
J_0(\epsilon) = \epsilon + \frac{1}{2}, \quad \epsilon > \frac{1}{2}. \quad (A21)
\]
Consequently, the integral (A19) can be expressed as
\[
\rho(\epsilon) = \rho_1(\epsilon) + \rho_2(\epsilon),
\]
\[
\rho_1(\epsilon) = \int_0^{\sqrt{2\epsilon}} dJ \frac{C_0^2(\epsilon, J)}{2} [\text{Im}(1_{\epsilon, J}) + \text{Im}(1, \epsilon, J)]^2,
\]
\[
\rho_2(\epsilon) = \quad \Theta(\epsilon - \frac{1}{2}) \int_{\sqrt{2\epsilon}}^{\epsilon + 1/2} dJ \frac{C_0^2(\epsilon, J)}{2} [\text{Im}(1_{\epsilon, J})]^2,
\]
(A22)
where the notations
\[
\text{Im}(1_{\epsilon, J}) = \int_{x_1}^{x_2} \frac{dx}{v_x} \int_{x_1}^{x_2} \frac{dx}{v_x} \frac{\epsilon \sqrt{\epsilon^2 + k^2}}{x}, \quad x_1 < 1; \quad (A23)
\]
\[
\text{Im}(1_{\alpha, \epsilon, J}) = \int_{\alpha}^{\sqrt{b_+}} \frac{dx}{v_x} (\epsilon + \frac{1}{2} - \frac{1}{2} x^2), \quad \alpha \geq 1,
\]
are introduced; \(C_0^2(\epsilon, J)\) is given by Eq. (A15), and \(v_x\) is determined by Eqs. (A16), (A17). Note that here we have employed the explicit expressions (A11)- (A13) for the turning points.
The value of the normalization constant \(C_0\) can be found explicitly [27]. The integrals (A23) can also be calculated explicitly. We find
\[
\frac{C_0^2(\epsilon, J)}{2} = \frac{2}{\pi}, \quad \text{In}_2(\sqrt{\beta - \epsilon}, \epsilon, J) = \frac{\pi}{4}(\epsilon + \frac{1}{2}), \quad (A24)
\]
for \(\epsilon > 1/2, \sqrt{2\epsilon} < J < \epsilon + 1/2\), and
\[
\frac{C_0^2(\epsilon, J)}{2} = \left(\frac{2\epsilon \arccos \alpha_1}{\sqrt{2\epsilon^2 + J^2}} + \arccos \alpha_2\right)^{-1},
\]
\[
\text{In}_1(\epsilon, J) = \frac{\epsilon^2 \arccos \alpha_1}{\sqrt{2\epsilon^2 + J^2}} + \frac{1}{4}\sqrt{2\epsilon - J^2} - \frac{1}{2\sqrt{2}} \ln \alpha_3,
\]
\[
\text{In}_2(1, \epsilon, J) = \frac{1}{2}(\epsilon + \frac{1}{2}) \arccos \alpha_2 - \frac{1}{4}\sqrt{2\epsilon - J^2},
\]
for \(J < \sqrt{2\epsilon}\), where we have introduced the notations
\[
\alpha_1 = \sqrt{\frac{2\epsilon^2 + J^2 - \epsilon + \epsilon \sqrt{1 + 4\epsilon^2 + 2J^2}}{2\epsilon \sqrt{1 + 4\epsilon^2 + 2J^2}}},
\]
\[
\alpha_2 = \sqrt{\frac{1}{2} - \epsilon + \sqrt{(\epsilon + \frac{1}{2})^2 - J^2}} - \frac{1}{2}\sqrt{(1 + \frac{1}{2})^2 - J^2},
\]
\[
\alpha_3 = \frac{1}{\sqrt{2}}\left[\sqrt{1 + 2\epsilon - \sqrt{1 + 4\epsilon^2 + 2J^2} + \sqrt{1 + 2\epsilon + \sqrt{1 + 4\epsilon^2 + 2J^2}}}\right]^{1/4},
\]
\[
(1 + 4\epsilon^2 + 2J^2)^{-1/4}.
\]
We note that in the formal limit \(\beta \gg 1\), the function \(D(\beta)\) given by (A18) can be found explicitly. Indeed, in this case the main contribution to (A19) comes from \(\epsilon \gg 1\). This implies that only the term \(\rho_2(\epsilon)\) in Eq. (A22) should be taken into account because it gives the highest power of \(\epsilon\) as \(\rho_2(\epsilon) \sim \epsilon^4\). As simple analysis of (A22) shows, the term \(\rho_1(\epsilon) \sim \epsilon^3\). Thus, taking \(\rho(\epsilon) \approx \rho_2(\epsilon)\) and combining Eqs. (A24), (A22), (A25) and (A12), we find
\[
\rho(\epsilon) = \frac{\pi}{16}(\epsilon^2 - \frac{1}{4})^2 \Theta(\epsilon - \frac{1}{2}) \approx \frac{\pi}{16} \epsilon^4,
\]
for \(\epsilon \gg 1\). Substituting this into (A18) and taking the limit \(\beta \gg 1\), we obtain
\[
D(\beta) \approx \sqrt{\frac{3\pi}{2}} \beta^{5/2},
\]
which yields Eq.(38). This expression is shown in Fig.1 by the dashed line. As one can see, in the range of \(\beta\) of

the order of 1 the approximation (A28) underestimates the rate by approximately 20%.

We note that actual values of \(\beta = T/2\mu\) are far from being \(\beta \gg 1\). Indeed, employing Eqs. (A2) and (37), we find
\[
\beta = \frac{T}{2\mu} = \left(\frac{\tau_{ho}}{15\alpha}\right)^{2/5} \zeta^{-1/3}(3)N^{-1/15} \frac{T}{T_c},
\]
which yields values \(\beta \approx 1\) for the experiment [10] for \(T \approx T_c\). Therefore, for these values the function \(D(\beta)\) should be found numerically (see the solid line in Fig.1).

In the opposite limit \(\beta \rightarrow 0\), which corresponds to \(T << 2\mu\) or large \(N\), the contribution to \(D(\beta)\) due to \(\rho_2(\epsilon)\) becomes exponentially small. Thus, the term \(\sim \rho_1(\epsilon)\) (A22) dominates in (A18). Taking into account that the effective values of \(\epsilon \sim \beta\), one may perform an expansion in terms of the small parameter \(\epsilon\) in Eqs.(A26), (A25) and obtain
\[
\rho(\epsilon) \approx \rho_1(\epsilon) = \rho_{01} \epsilon^{7/2}, \quad \epsilon \rightarrow 0,
\]
where the notation
\[
\rho_{01} = \int_{0}^{\pi/2} dx \sin x \frac{\left[x + \frac{1}{\pi} \sin 2x(7 + 11 \cos^2 x)\right]^2}{x + \frac{1}{\pi} \sin 2x}
\]
has been introduced. A numerical evaluation of this integral gives \(\rho_{01} \approx 1.5\). This yields for (A18)
\[
D(\beta) \approx D_{01} \beta^{9/4},
\]
\[
D_{01} = \left[\rho_{01} \int_{0}^{\infty} dx \left(e^{-x^2/2}\right)^{7/2}\right]^{1/2} \approx 4.4
\]
in the limit \(\beta << 1\).

**APPENDIX B: CALCULATION OF THE AMPLITUDE DEPENDENCE OF THE DEPHASING RATE**

Expanding Eq.(29) up to the third order with respect to \(\eta\), one gets
\[
\ddot{\eta} + \omega_M^2 \eta - \alpha_M \eta^2 + \beta_M \eta^3 = 0,
\]
where the notations are
\[
\omega_M^2 = (5 - \xi)\omega_{ho}^2, \quad \alpha_M = 10(1 - \frac{\xi}{3})\omega_{ho}^2, \quad \beta_M = 20(1 - \frac{\xi}{3})\omega_{ho}^2.
\]
The solution of (B1) up to the second order with respect to \(\eta_0\) has a form
\[
\eta = \frac{2\alpha_M}{\omega_M^2} |\eta_0|^2 + (\eta_0 e^{i\omega t} + c.c.) - \frac{\alpha_M}{3\omega_M^2} (\eta_0^2 e^{i\omega t} + c.c.),
\]
}\[
where the effective frequency \( \omega \) in the same order is

\[
\omega = \omega_M + \omega' |\eta_0|^2, \quad \omega' = -\frac{5\alpha^2 M^2}{3\omega_M^3} + \frac{3\beta M}{2\omega_M^2}.
\]  

(B4)

Now employing (B2) in (B4) and performing the thermal averaging of (B1) over \( \xi \) in the limit \( \xi << 1 \), we obtain

\[
\langle \eta \rangle_T = \eta_0 e^{i\omega t - t^2/\tau_{dM}(A_1)} + c.c.,
\]

(B5)

where the constant as well as the second harmonic have been omitted; the dephasing rate \( 1/\tau_{dM}(A_1) \) as a function of the amplitude \( A_1 = 2\eta_0 \) of the first harmonic is given by Eq.(39).
