We study the continuum limit of adjoint SU(2) LGT by means of a suppression term for $\mathbb{Z}_2$ monopoles. High barriers for tunnelling among different twist sectors are overcome through parallel tempering. Monopole condensation is used to study the deconfinement transition and the properties of the confined phase. Ergodicity in summing over all twist sectors allows an unbiased measure of the ’t Hooft vortices free energy. Its behaviour in the SO(3) confined phase hints at differences from what conjectured for semi-integer discretizations.

XXIIIrd International Symposium on Lattice Field Theory
25-30 July 2005
Trinity College, Dublin, Ireland

∗Speaker.
1. Introduction

The spontaneous breaking of center symmetry [1] observed in simulations of pure fundamental lattice Yang-Mills theories has offered unique insight in their still elusive dynamics [2]. Whether and in what sense this holds for the perturbatively equivalent center-blind adjoint discretization, as universality predicts [3], must still be appropriately answered [4]. The difficulties inherent to such non-perturbative regularization have been well known for along time [5] and are best illustrated by the phase diagram of the mixed action, which for SU(2) reads

\[ S = \beta_A \sum_P \left( 1 - \frac{1}{3} \text{Tr} A_P U_P \right) + \beta_F \sum_P \left( 1 - \frac{1}{2} \text{Tr} F_P U_P \right); \]

\[ \frac{1}{g^2} = \frac{1}{4} \beta_F + \frac{2}{3} \beta_A. \]

(1.1)

The theory exhibits bulk transitions related to the condensation of \( \mathbb{Z}_2 \) monopoles \( \sigma_c \in \text{SO}(3) \) and vortices \( \sigma_l \in \text{SU}(2) \) which hinder the study of its finite temperature properties [6]. First concrete attempts to study its at finite temperature by implementing suppressing chemical potentials \( \lambda \sum_c (1 - \sigma_c) \), \( \gamma \sum_l (1 - \sigma_l) \), as suggested in [6], were only made relatively recently [7]. For the center blind case \( \beta_F = 0, \gamma = 0 \), where the bulk transition separates a strong coupling phase I, continuously connected with SU(2), from a weak coupling phase II, there is no symmetry breaking mechanism and no order parameter. In these works it was however first observed how in such pure adjoint case at high temperature the theory possesses, besides the “regular” deconfined phase where the adjoint Polyakov loop \( L_A \rightarrow 1 \), a new phase where \( L_A \rightarrow -1/3 \). In [8] a dynamical observable measuring the twist expectation value \( z \) was introduced after noting that the \( \delta (\sigma_c - 1) \) constraint effectively implemented by \( \mathbb{Z}_2 \) monopole suppression allows the SO(3) partition function to be rewritten as the sum of SU(2) partition functions with all possible twisted boundary conditions \( Z_{z=1} \). The \( L_A \rightarrow -1/3 \) phase was linked to a non trivial twist expectation value, i.e. to the creation of a vortex in the vacuum. The SO(3) theory was proposed as the ideal test case to check the ’t Hooft vortex confinement criterion [10]. Unfortunately twist sectors freeze at the bulk and attempts with a multicanonical algorithm at \( \lambda = 0 \) have been limited to volumes not higher then \( 8^3 \times 4 \) [8]. Other attempts to study the existence of a finite temperature transition in phase II with \( \lambda \neq 0 \) through thermodynamic observables were limited to very small temporal extent \( N_\tau = 2 \) [11], confirming that the continuum limit is a real challenge for the adjoint theory. A step forward was made in [12, 13], where by means of the Pisa disorder parameter for monopole condensation lines of second order transition properly scaling with \( N_\tau \) and ending on the bulk where actually found at each fixed twist, with critical exponents consistent with Ising 3-d. Whether such is the case also for the theory summed over all twist sectors and how the vortex free energy behaves in the ergodic simulations is the subject of the present preliminary report, based on the poster presented at this conference. A complete analysis of the model with updated results, including a detailed description of the algorithm and error analysis can be found in [14, 15].

2. Action and Observables

As anticipated, we will concentrate on the pure adjoint Wilson action (Eq. (1.1)) with \( \beta_F = 0 \), modified by the suppression term \( \lambda \sum_c (1 - \sigma_c) \), where \( \sigma_c = \prod_{P \in \partial c} \text{sign} (\text{Tr} F_P U_P) \) around all elementary 3-cubes \( c \) defines the \( \mathbb{Z}_2 \) magnetic charge. Its density \( M = 1 - \langle \frac{1}{N_\tau} \sum_c \sigma_c \rangle \) tends to
Ergodic SO(3), monopole condensation and vortex free energy

Giuseppe Burgio

one in the strong coupling region (phase I) and to zero in the weak coupling limit (phase II), \(N_c\) denoting the total number of elementary 3-cubes. Such action is center-blind in the entire \(\beta \lambda - \lambda\) plane \([16]\). We will employ parallel tempering to obtain ergodicity among different twist sectors when evaluating the expectation values of physical observables, e.g. the Pisa disorder parameter and the ’t Hooft vortex free energy.

2.1 Vortex Free Energy

Temporal twists, corresponding to maximal ’t Hooft loop and defining our center vortices, are topological excitations which offer a natural link between center symmetry breaking and degrees of freedom independent of the discretization used \([10]\). It has been known for a long time in the literature that SO(3) with \(\mathbb{Z}_2\) monopole chemical potential in phase II is equivalent to SU(2) including all possible twisted b.c. \([9]\)

\[
\sum_{\text{b.c.}} Z_{\text{SU}(2)} = \int (DU)e^{-S_{\text{SO}(3)}} \prod_c \delta(\sigma_c - 1) \simeq Z_{\text{SO}(3)} \mid_{\lambda \to \infty} .
\]

(2.1)

Above the bulk SO(3) trades thus boundary conditions with twist sectors. Twists, i.e. ’t Hooft loops, thus become observables rather than boundary constraints like in SU(2):

\[
z_i = \frac{1}{N_s^2} \sum_{j \neq i} \prod \text{sign}(\text{Tr}_f U_{i,j}(x)) .
\]

(2.2)

Since creating such ’t Hooft loop amounts to a change in the signs of some plaquettes, the free energy change \(\Delta F = \Delta U - T \Delta S\) will only receive an entropy contribution for adjoint discretizations, the action remaining unmodified in the process. Defining thus the ’t Hooft vortex free energy as the ratio of the partition function in the non-trivial twist sector to that in the trivial one \(F = -T \log Z_{\mid z = 1}/Z_{\mid z = 0}\), their relative weight can be measured through an egodic simulation. To be an order parameter in the thermodynamic limit \(V = N_s^3 \to \infty\), \(F\) should vanish exponentially in the confined phase while diverging with an area law \(F \sim \tilde{\sigma} N_s^2\) above the deconfinement transition, where \(\tilde{\sigma}\) is the dual string tension. Working at \(\lambda = 0\) proved however to be a hurdle, since the “freezing” of twist sectors above the bulk transition yields high potential barriers hard to overcome even with a multi-canonical algorhythm \([8]\). From the results in \([16, 17, 18, 19, 20]\) it is sound to conjecture that the whole physically relevant SO(3) dynamics lies in phase II, the finite temperature transition eventually decoupling from the bulk even at \(\lambda = 0\). Unfortunately, from estimates in \([8]\), this should not happen for volumes smaller than \(\sim 500 \times 1000^3\). A non-vanishing \(\lambda\) seems therefore the only feasible way to gain access to the properties of the continuum limit of SO(3). The observation made in \([7]\) that the bulk transition weakens to 2nd order with increasing \(\lambda\) will prove crucial in this respect.

2.2 Pisa disorder parameter

The Pisa disorder operator, measuring monopole condensation, is an order parameter for the dual superconductor mechanism of confinement \([21]\): defined through \(S_M\), the action modified through a bosonic field \(\Phi\) introduced at fixed time and invariant under a residual gauge simmetry
Ergodic SO(3), monopole condensation and vortex free energy

Giuseppe Burgio

U(1). It is independent of the particular choice for $\Phi$ and is well defined, independently of center symmetry, also for full QCD. Its derivative, $\rho$, is easier to compute in actual numerical simulations.

$$\langle \mu \rangle = \frac{\int (DU)e^{-(S_M-S)}e^{-S}}{\int (DU)e^{-S}} = \exp\left(\int_0^\beta \rho(\beta')d\beta'\right)$$

(2.3)

For $T < T_c$ $\langle \mu \rangle \neq 0$ signals spontaneous breaking of U(1), corresponding to $\rho \sim 0$, bounded from below for $N_s \to \infty$. At the phase transition $\rho$ should show a sharp negative peak at $\beta_c$ diverging for $N_s \to \infty$, while for $T > T_c$ $\langle \mu \rangle = 0$ corresponds to the trivial vacuum ($\rho \propto -N_s$ for $N_s \to \infty$). More details regarding its implementation for SO(3) can be found in [12, 13].

3. Fixed twist dynamics

It was shown in [13] that for SO(3) in phase II at fixed twist at low $\beta_A$ $\rho \sim 0 \forall z$, i.e. there always exists a confined phase; $\rho$ peaks at some ($z$ dependent!) $\beta_A'$; at high $\beta_A$ $\rho$ diverges for $z = 0$, while it vanishes for $z \neq 0$. Moreover each $z$ sector can be mapped in a different positive plaquette model. This makes fundamental observables measurable, while the adjoint sector remains untouched. It was thus proven that different twists possess slightly different underlying fundamental dynamics in the confined phase, but very different ones above deconfinement, the twist behaving effectively like a background field. Each twist sector measures slightly different string tensions in the confined phase (through Creutz ratios and Polyakov loop correlators) and deconfinement temperatures. From the above fixed twist measurements it is thus straightforward to see that the ergodic expectation value of $\mu$

$$\langle \mu \rangle = \frac{\sum_i \mu_{Z_{SO(3)}|z=i}}{\sum_i Z_{SO(3)}|z=i}$$

(3.1)

at low $\beta_A$ will be $\langle \mu \rangle \simeq 0$, while at high $\beta_A$ $\langle \mu \rangle \simeq \langle \mu \rangle_{z=0}(1 - e^{-F/T})$. In whole phase II ergodic theory confines at low $\beta_A$, deconfines at high $\beta_A$. To establish whether $\mu$ actually is an order parameter its behaviour at the physical transition must be studied through an ergodic algorithm.

4. Parallel Tempering

The idea of Parallel tempering (see [22] for a review) is to simulate at the same time many ensembles above and below the bulk transition. Each ensemble is characterized by a link-configuration $C_i$ and a set of couplings $\beta_i$. To reach ergodicity one lets them evolve separately swapping every few MC steps the $i^{th}$ and $(i-1)^{th}$ ensemble through a generalized Metropolis step with weight:

$$W_i = e^{-(S(\beta_i,C_i-1)+S(\beta_{i-1},C_i))+(S(\beta_i,C_i)+S(\beta_{i-1},C_{i-1}))}$$

(4.1)

As Fig. 1 shows it works very well, although it is crucial to fine tune the parameters to optimize acceptance rate and keep auto- and cross-correlations under control [14, 15]. Since phase I has a high tunnelling probability, the softening of the bulk transition to 2nd order is crucial to "transport" tunneling into phase II. Working on the 1st order bulk branch would lead to high barriers and thus no ergodicity at high volume.
Figure 1: MC history of twists and $L_A$ on top (left) and above bulk (right), $V = 16^3 \times 4$.

5. Results

As explained in Sect. (3), we need to establish whether $\rho$ gives a clear signal for a phase transition through ergodic runs. This is shown in Fig. (2-right). Due to the algorithm, we must choose a path that starts close to the bulk and goes above the deconfinement transition, with both not too far away from each other. Such path gives competing effects, since $\rho$ also diverges at the bulk [12, 13]. As for $F$, in phase I and at high $\beta_A$ it behaves as expected. The surprise comes in the confined phase of phase II, where the free energy doesn’t vanish (Fig. 2-left) We checked that away from both transitions $F$ reaches constant, $\beta_A$ dependent negative values throughout the confined phase of phase II.

Figure 2: Pisa disorder operator (right) and vortex free energy (left).

6. Conclusion and Outlook

We study the finite temperature transition in the continuum limit of SO(3) lattice gauge theory. Sum over twists for ergodicity is reached through Parallel tempering. The Pisa disorder parameter
Ergodic SO(3), monopole condensation and vortex free energy

Giuseppe Burgio

is used to characterize the properties of the different phases, so that Monopole (de)condensation could be used to obtain the critical exponents. Although well defined for SO(3), the ’t Hooft vortex free energy behaves unexpectedly, being negative in the confined phase of SO(3). The meaning of such vortex enhancement could be relevant for the dynamics of continuum Yang-Mills theories. However, contrary to $\mu$, $F$ seems not to behave as an order parameter in the theory discretized without fundamental components. Keeping in mind the full QCD case, there actually seems to be no compelling reason why in a center-blind regularization of Yang-Mills theory an order parameter for center symmetry breaking should vanish. Universal, representation independent observables should however be preserved, so further confirmations of the correct physical behaviour of the adjoint dynamics through e.g. the glueball spectrum might therefore be interesting. Also, the extension to SU(3) should shed further light on the problem. For further discussions and a more detailed analysis refer to [14, 15].
