Abstract Contagious bovine pleuropneumonia (CBPP) is a severe infectious disease caused by Mycoplasma mycoides subsp. mycoides. The peculiar pathological features of CBPP make desirable the assessment of ad hoc score methods to grade the disease in the affected animals. Thus, the present work aims to assess a new lung score system for CBPP. Our results indicate that the present score system strongly correlates with that previously published by Turner and could be effectively used in CBPP-affected animals.

Introduction

Respiratory diseases commonly occur in all animal species and notably impact upon the profitability of farms, both directly (mortality, poor daily weight gain) and indirectly (costs for antimicrobial drugs, vaccines, veterinary cares, etc.). The etiology of respiratory diseases is usually considered multifactorial and involves a number of risk factors, which can be grouped and summarized as follows:

a) management—overcrowding, commingling with animals from multiple sources, environmental conditions such as temperature, humidity, dust levels;
b) individual factors—age, breed, immune status, concurrent diseases;
c) pathogens—viruses, bacteria, parasites (Taylor et al. 2010).

Considering that the correct diagnosis is crucial for the efficient treatment and/or prevention of respiratory diseases. Pathological findings observed at necropsy are extremely useful to make a rapid, presumptive diagnosis, as well as to drive further laboratory investigations. In addition, postmortem inspections allow “scoring” of lung lesions, such assessment being essential in order to evaluate the efficacy of the therapeutic and/or preventive measures undertaken.

The assessment of reliable, standardized lung score systems, which can easily be carried out even under field conditions (e.g., at the slaughterhouse), has been required for a long time to assess the health status of animal populations. A number of methods have been proposed also for bovine respiratory diseases, including contagious bovine pleuropneumonia (CBPP; Table 1).

CBPP is a severe infectious disease caused by Mycoplasma mycoides subsp. mycoides (Mmm), which is still widespread and of major economic significance in sub-Saharan Africa (Anonymous 2014; Thiaucourt et al. 2004). CBPP-induced lesions vary during the course of the disease, as shown in Fig. 1. The peculiar pathological features of CBPP make the assessment of ad hoc lung lesion score systems desirable. In this respect, Turner (1961) developed a specific method to score CBPP lesions (Table 2). Although widely used, we consider that Turner’s scoring system shows some “weak points” (e.g., it does not consider pleurisy), which would be hopefully overcome.
On the basis of the above considerations, the main goals of the present paper are to assess a new lung lesion score system for CBPP and to compare it with Turner’s method.

### Materials and methods

A total of 98 “zebuine” cattle, experimentally infected with *Mmm* by intubation (*n* = 56) or by contact (*n* = 42), have been included in the present study. Experimental investigations were carried out in Namibia (2004) and Zambia (2016), according to the animal testing regulations applied therein.

Cattle were culled and subjected to in-depth postmortem inspection. The lungs were first observed in situ, after opening the thoracic cavity, then removed and carefully inspected physically by skilled veterinarians (Fig. 2).

As shown in Fig. 3, the lungs were subdivided into 11 “areas”, which were similar in volume. At first, the lungs were visually inspected to notice the presence, if any, and the extent of acute (fibrinous) and/or chronic (adhesive) pleurisy. The

The score was calculated as the pneumonic percentage of each lobe multiplied for a lobe-specific corrective factor |
| Leruste et al. (2012).   | To evaluate the relationship between clinical signs and lung lesions at slaughter | Visual inspection of the lungs. Score 0–3 for the entire lung parenchyma         |
| White et al. (2012);     | To study the relationship among clinical signs, behavioral changes, and lung lesions in *Mycoplasma bovis*-infected calves | The score was calculated by multiplying the percentage of consolidation in each lobe by the proportion of the total lung that each lobe represented |
| Amrine et al. (2013).    |                                                                      |                                                                                  |
| Turner (1961).           | To evaluate the efficacy of vaccination against CBPP                  | Two points for acute or necrotic lesions; one point for healing process. Such scores were multiplied by a severity factor (1 to 3) according to the size of the lesions. Possible scores = 0, 1, 2, 4, and 6 |

*CBPP* contagious bovine pleuropneumonia

![Fig. 1: Main pathological findings in CBPP-affected cattle.](image-url)
The presence of pleurisy scored 1 point per each affected area; as a result, the pleurisy score ranged between 0 and 11.

Then, the lungs were evaluated by palpation, and all foci of consolidation were assessed on cut section; to that aim, the entire thickness of the lung was cut perpendicularly to its main axis. Each lesion was evaluated at its largest point and photographed. Pathological features (red and gray hepatization, necrosis, sequestra, fibrosis) were recorded in each area and scored as follows:

- 0 points = absence;
- 1 point = < 25% of the cutting section;
- 2 points = 25–50% of the cutting section;
- 3 points = 50–75% of the cutting section;
- 4 points = > 75% of the cutting section.

Small-size sequestra (“microsequestra”, < 1.5 cm in diameter) did not fit in the above categories and were scored on the basis of their number.
Using this method, the maximum possible score amounted to 55 (explanatory examples are provided in Fig. 4). All recorded data were reported in a file format of Microsoft Excel, thus being available for statistical processing.

Results

The pathological assessment of each animal was rapid. The scores resulting from both methods are reported in Table 3. The features and the severity of CBPP lesions were highly variable. Pleurisy was observed in 81 cattle, it was acute (fibrinous pleurisy, $n = 17$) or chronic (pleural adhesion, $n = 64$), most commonly affected the diaphragmatic lobes and overlaid pneumonic foci. Acute/subacute lung lesions (red and gray hepatization, respectively) were detected in 15 animals, while areas of pulmonary necrosis were seen in 28 cattle. In chronic cases, fibrosis ($n = 17$), sequestra ($n = 42$), and microsequestra ($n = 21$) were detected.

As a consequence, scores also largely varied, ranging between 0 and 6 and 1–55 (Turner’s and “new CBPP score system”, respectively). The two scoring systems appeared positively and strongly correlated, the Pearson’s coefficient being 0.71.

Discussion

Postmortem assessment of lesions provides valuable information to manage the health status in livestock. Up to date, that proposed by Turner is the only suitably developed method to score CBPP lesions. Although useful and easy to perform
under field conditions, this method shows some limitations, as it does not cater to all categories of CBPP lesions.

First of all, the Turner scoring system does not consider pleurisy which, in our experience, could be the only relevant lesion at the time of postmortem inspection, mostly in vaccinated and/or experimentally infected and/or naturally recovering cattle. Moreover, the Turner system only partially distinguishes CBPP lesions on the basis of their features (i.e., the stage of development) and size; for example, an animal with a large sequestrum (> 20 cm in diameter) gets the maximum score (6 points), in the same way as one with a diffuse, bilateral, acute-to-subacute pleuropneumonia. Scoring lung lesions according to their size (expressed in cm) could also raise some concerns, considering that cattle size can vary widely among breeds.

Aiming to “mitigate” such limitations, we designed the present lung lesion score system, which summarizes those previously

### Table 2 CBPP score system proposed by Turner (1961)

| Pathological features          | Multiplying severity factor (size of lesion) |
|--------------------------------|---------------------------------------------|
|                               | 1–5 cm | 6–20 cm | > 20 cm |
| Acute-to-necrotic lesions      | 2 points | ×1   | ×2   | ×3   |
| Total score =                 | 2      | 4     | 6     |
| Fibrosis, resolving lesions   | 1 point | ×1   | ×2   | ×3   |
| Total score =                 | 1      | 2     | 3     |

As shown in the Table, this system allots 1 point if only fibrotic/resolving lesions are observed, while 2 points are assigned to acute-to-necrotic lesions. Such scores are multiplied for a severity factor, which ranges between 1 and 3 and depends on the size of lesion. Therefore, the maximum possible score is 6 points.

### Table 3 Comparison of data obtained by the two different lung score systems

| ID | Tumer | New | ID | Tumer | New | ID | Tumer | New | ID | Tumer | New |
|----|-------|-----|----|-------|-----|----|-------|-----|----|-------|-----|
| 1  | 2     | 2   | 26 | 4     | 5   | 51 | 4     | 7   | 76 | 3     | 2   |
| 2  | 2     | 1   | 27 | 2     | 6   | 52 | 4     | 5   | 77 | 0     | 1   |
| 3  | 4     | 4   | 28 | 2     | 6   | 53 | 1     | 3   | 78 | 1     | 4   |
| 4  | 0     | 4   | 29 | 2     | 6   | 54 | 6     | 12  | 79 | 6     | 7   |

*ID* identification number of each animal included in the present study, *Tumer* CBPP lung score system proposed by Turner (1961), *New* new proposal for CBPP lung score system
published by other authors and is herein considered useful to quantify CBPP lesions. As an example, our system partly overlaps the “consolidation lung lesion score”, which also splits the lungs in “areas” and is currently recommended by the European Pharmacopeia for porcine pleuropneumonia (Sibila et al. 2014).

Although apparently complicated, the present method requires a few minutes to assess individual animals; at the same time, collected data provide in-depth information about the stage (acute-to-chronic) and the severity of the disease. In addition, disaggregated data—recorded in a file format of Microsoft Excel—could allow for a number of additional considerations, useful to evaluate the effect of therapeutic/preventive measures.

The natural challenge in cattle by the in-contact method is the only way to control the potency of a vaccine against CBPP (Anonymous 2014). Therefore, the assessment of well-detailed lung score systems could fill such gaps. In this respect, further investigations are needed to relate CBPP scores—obtained with this and/or other methods—with clinical, productive, and diagnostic parameters.

Experience has shown that taking pictures (detailed and of good quality) from all investigated cattle proved to be quite time-consuming, challenging, not easily standardized, and often unfeasible (Sibila et al. 2014). Nevertheless, it is worth planning such an activity, which allows a more precise, as well as retrospective evaluation of each CBPP-affected animal. In addition, these pictures could be available for “digital scoring” of lesions.

In conclusion, the present scoring method strongly correlates with that proposed by Turner (1961), which was the only CBPP-specific lung score system available, repeatedly used in experimental investigations to assess the efficacy of vaccines anti-CBPP. We consider that our lung score system adequately details the pathological findings observed in CBPP-affected cattle and could be effectively used, mostly in experimental studies, to evaluate the efficacy of preventive or therapeutic measures for CBPP.
