*Rhodopseudomonas palustris* CGA009 is a metabolically robust microbe that can utilize lignin breakdown products to produce polyhydroxyalkanoates (PHAs), biopolymers with the potential to replace conventional plastics. Our recent efforts suggest PHA granule formation is a limiting factor for maximum production of the bioplastic poly(3-hydroxybutyrate-co-3-hydroxyvalerate) (PHBV) by *R. palustris*. The Phap1 phasin (*phaP1*) from the PHB-producing model bacterium *Cupriavidus necator* H16 was expressed in *R. palustris* with the aim of over-producing PHBV from the lignin breakdown product p-coumarate by fostering smaller and more abundant granules. Expression of *phaP1* yielded PHBV production from *R. palustris* aerobically (0.7 g/L), which does not occur in the wild-type strain, and led to a significantly higher PHBV titer than wild-type anaerobic production (0.41 g/L). The 3HV fractions were also significantly increased under both anaerobic and aerobic conditions, which boosts thermomechanical properties and potential for application. Thus, heterologous phasin expression in *R. palustris* provides flexibility for industrial processing and could foster compositional changes in copolymers with better thermomechanical properties compared to PHB alone.

**1. Introduction**

Polyhydroxyalkanoates (PHAs) are biopolymers produced by bacteria that have the potential to replace conventional plastics due to their similar thermomechanical properties, biodegradability, and biocompatibility (Li et al., 2016; Muneer et al., 2020; Sabbagh and Muhamad, 2017). Due to these characteristics, PHAs have been applied in a wide variety of applications including therapeutics, packaging, and environmental rehabilitation (Bello-Gil et al., 2018; Draper and Rehm, 2012; Hungund et al., 2018; Parlane et al., 2017). Bacteria typically produce PHAs in response to stressful conditions, such as unbalanced growth, and store the granules inside the cell as a means of carbon and redox balance (Koller, 2020). The most commonly produced PHA by bacteria is called poly-3-hydroxybutyrate (PHB) and is thus the most extensively studied. However, market acceptance of PHAs is limited by their relatively high production costs compared to conventional plastics (Aramvash et al., 2018). PHA costs depend mainly on the carbon source, fermentation technology, and extraction processes (Chen et al., 2020; Medeiros et al., 2020). Approximately half of the production cost for PHAs derives from the carbon source (Raza et al., 2018). Thus, engineering a microbe for PHA production from cheaper and renewable carbon sources is necessary to promote the valorization of PHAs.

Lignocellulosic biomass is considered to be the most economic carbon source in the world and is thus an ideal candidate for cheaper production of bioplastics (Ponnsamy et al., 2019; Qian, 2013). Using inexpensive and renewable carbon sources for bioplastic production that do not compete with food production, such as lignocellulosic biowaste, could significantly reduce the costs of bioplastics while simultaneously closing the carbon loop. Lignin is a heterogeneous network of cross-linked aromatics that accounts for nearly 30% of the organic carbon in plant biomass (Ponnsamy et al., 2019). The production of biopolymers from lignin is arguably one of the most promising routes for boosting the valorization of lignin (Rajesh Banu et al., 2019). Yet, one of the major challenges for valorizing lignin is developing an efficient biocconversion process to create value-added bioproducts from lignin breakdown products (LBPs), such as monolignols and hydroxycinnamic acids. Unfortunately, most microorganisms that can produce...
high-valued bioproducts cannot metabolize LBPs and are even inhibited by them. Thus, employing synthetic biology techniques and metabolic engineering to over-produce PHAs from microbes capable of catabolizing this cheaper and renewable carbon source is ideal. Efforts in synthetic biology and metabolic engineering offer opportunities for overproduction of PHAs (Koller, 2017; Raza et al., 2018), but there is still a need to engineer a microbe for more cost-competitive production of PHAs from lignocellulosic biomass.

Bacteria that produce PHAs utilize an ensemble of granule-associated proteins (GAPs) that help balance metabolic tradeoffs in cell growth, PHA production, and other functions. This system of GAPs includes polymerases, depolymerases, synthases (PhaC), phasin regulators, overproduction of PHAs (Koller, 2017; Raza et al., 2018), but there is still a need to engineer a microbe for more cost-competitive production of PHAs from lignocellulosic biomass. GAPs include pathways for three of the four known microbial lignin degradation strategies, incorporating both aerobic and anaerobic photo-synthetic catabolism (Larimer et al., 2004). Thus, *R. palustris* can break down numerous aromatic compounds derived from lignin while also potentially accomplishing complete degradation of these compounds to intermediates in the citric acid cycle that are important building blocks for bioplastic development. Our recent works show that *R. palustris* can utilize the major LBPs p-coumarate and coniferyl alcohol to produce bioplastics (Alishyabi et al., 2021; Brown et al., 2020). We also revealed that *R. palustris* can create a copolymer of PHB called poly(3-hydroxybutyrate-co-3-hydroxyvalerate) (PHBV), which is a copolymer of the 3-hydroxybutyrate (3HB) and 3-hydroxyvalerate (3HV) monomers that has more ideal thermomechanical properties compared to PHB alone (Li et al., 2016).

In this study, *phaP1* from *C. necator* H16 was expressed in *R. palustris* with the aim of overproducing PHAs from lignocellulosic sources. *R. palustris*’ ability to produce PHBV from lignocellulosic biomass renders it an ideal candidate for engineering toward industrial PHA production from lignin. However, our recent efforts also revealed that granule formation may be a limiting factor for maximum PHBV production due to one large PHBV granule formed inside the cells (Alishyabi et al., 2021). Thus, heterologous expression of *phaP1* was implemented in *R. palustris* with the aim of overproducing PHBV from lignocellulosic biomass by fostering smaller and more abundant granules to utilize more of the intracellular space.

### 2. Materials and methods

#### 2.1. Growth curves and PHBV production

*R. palustris* seed culture was grown on photosynthetic media (PM) supplemented with 20 mM sodium acetate to an OD$\text{_{660}}$ of approximately 1.
supplemented with kanamycin (300 μg/mL) to serve as a control for assessing PHBV production. Data points are averages of biological triplicates, and errors bars are the calculated standard deviation. All conditions were grown on 1 mM p-coumarate and 10 mM sodium bicarbonate.

0.5 as described previously (Brown et al., 2020). All conditions employing the phiP1 and backbone plasmid (pBBR1MCS-2) strains were supplemented with kanamycin (300 μg/mL). Cultures were diluted to an OD<sub>600</sub> of 0.2 in fresh PM supplemented with 1 mM p-coumarate and 10 mM sodium bicarbonate as the carbon sources in anaerobic and aerobic conditions. Anaerobic cultures were grown in sealed 14 mL Falcon™ round-bottom polystyrene tubes at 30 °C with 100 μL of fresh PM and continuous shaking at 275 rpm. Falcon™ tubes were sealed to the second position via the secure snap-cap to provide a secure, positive seal. Oxygen depletion is assumed for anaerobic cultures after the tubes are sealed. Aerobic cultures were grown in the dark using 250 mL flasks with no more than 50 mL of total culture volume in each flask, at 30 °C, and with continuous shaking at 275 rpm. Growth data were fitted to a modified logarithmic growth model as described previously (Brown et al., 2020). For anaerobic conditions, cultures were nitrogen starved at mid-exponential growth by resuspending the cell pellet in fresh PM supplemented with 1 mM p-coumarate and 10 mM sodium bicarbonate. Anaerobic cultures were grown for 2 h, and washed twice with autoclaved H<sub>2</sub>O (Tu et al., 2016).

PHBV extraction and quantification was conducted as described previously (Brown et al., 2020). All harvested samples were washed twice with 1x phosphate buffered saline (PBS), stored as cell pellets in −80 °C until further processing, and extracted via acidic methanolysis. PHBV was quantified with conventional GC-MS as described (Brown et al., 2020), using serial dilutions of sodium 3-hydroxybutyrate or (−)-methyl (R)-3-hydroxyvalerate (Sigma-Aldrich™) as standard.

2.2. PHBV quantification via gas chromatography-mass spectrometry (GC-MS)

C. necator was grown on rich media (17.5 g/L nutrient broth, 7.5 g/L yeast extract, 5 g/L (NH<sub>4</sub>)<sub>2</sub>SO<sub>4</sub>) to an OD<sub>600</sub> of approximately 1.0 (Nangle et al., 2020). R. palustris was grown as described in Section 2.1. Chromosomal DNA was extracted using a Quick-DNA Fungal/Bacterial kit per manufacturer instructions (Zymo Research). The plasmid was constructed using the Hot Fusion assembly method (Fu et al., 2014). The oligonucleotides and plasmids are summarized in Table 1. The oligonucleotides were purchased from Eurofins Genomics. Enzymes were purchased from Thermo Fisher Scientific.

2.4. Strain construction

The PSSBIO32-tonB-phiP1 plasmid was constructed in NEB® 10-beta competent E. coli. E. coli was grown overnight, diluted to 0.025%, grown for 2 h, and washed twice with autoclaved H<sub>2</sub>O (Tu et al., 2016). The washed cells were transformed with the Hot Fusion products via electroporation. The electroporated cells were allowed to rest at 30 °C for 1–1.5 h in Luria Broth (LB) (Miller, AMRESCO) at 30 °C and 250 rpm in 14 mL BD Falcon™ round-bottom tubes without antibiotics, and subsequently plated onto LB plates supplemented with kanamycin (30

μg/mL). Colonies were selected and cultures were frozen as 15% glycerol stock at –80 °C until further processing. Fresh culture was subjected to the Invitrogen™ PureLink™ Quick Plasmid Miniprep kit (Thermo-Fisher) to remove the plasmid per manufacturer’s instructions. PCR using designed sequencing oligonucleotides was conducted with the plasmids, and gel electrophoresis was used to check the amplicon size. If the amplicon was the expected size, the reaction was purified with the PureLink™ Quick PCR Purification Kit (Thermo-Fisher), and submitted to Eurofins Genomics for sequencing.

Sequence-verified plasmids were transformed into R. palustris following the same washing and electroporation steps. The transformed cells rested in Van Niel’s Yeast Media (ATCC Medium 112) and were plated 24 h later on Van Niel’s Yeast Agar supplemented with kanamycin (300 μg/mL). Colonies were then streaked onto a new plate to supplement growth. Cells from this plate were lysed in water at 100 °C for 25 min. PCR with the designed sequencing oligonucleotides was conducted again, followed by gel electrophoresis to check the amplicon size, purification, and submission for sequencing.

2.5. RT-PCR reactions

To validate expression of phaP1, RT-PCR was conducted for the wild type and phaP1 strains under aerobic and anaerobic conditions using the designed oligonucleotides outlined in Table 1. Cultures were grown to mid-exponential on p-coumarate as shown in Fig. 1, saved with RNA-Later® solution per manufacture instructions, and stored in –80 °C until further processing. RNA was extracted according to conventional chloroform-phenol extraction, and RNA samples were rid of DNA using the Invitrogen™ TURBO™ DNA-Free Kit (ThermoFisher). The RNA samples were purified using the Monarch® RNA Cleanup Kit (New England BioLabs). All samples were confirmed DNA-free due to a lack of a positive band from RT-PCR using a certain cDNA sample, that sample was considered too low of quality for further analysis.

2.6. Transmission electron microscopy (TEM)

TEM was conducted to visualize granules inside the wild type and phaP1 strains grown on p-coumarate in both aerobic and anaerobic conditions as described previously (Alsiyabi et al., 2021). Briefly, the samples were fixed in a 2% glutaraldehyde and 1.5% paraformaldehyde in 100 mM sodium cacodylate buffer and submitted to the Nebraska Center for Biotechnology Morrison Microscopy Core Research Facility at the University of Nebraska-Lincoln. The samples were processed further by washing in sodium cacodylate buffer three times, and post-fixing in 1% osmium tetroxide in deionized water at room temperature for 1 h. The samples were dehydrated through an ethanol series, embedded in Spurr medium, ultrathin section were cut using a Leica UC7 ultramicrotome, and the sections were stained with 1% uranyl acid and 1% lead citrate. Images were collected using a Hitachi H7500 TEM and taken without selection or bias.

2.7. Metabolic modeling

The trade-off plot between PHB and biomass production for the phaP1 strain under aerobic conditions was generated by simulating (via flux balance analysis) aerobic growth on p-coumarate (Orth et al., 2010) using R. palustris genome-scale metabolic model iRpa940 (Alsiyabi et al., 2019, 2021). The maximal PHB and biomass generation rates were first determined by maximizing their respective reactions in the model. Next, biomass production was maximized while PHB production rate was set to increasing values between zero and maximal production. The maximum rate of carbon fixation was assumed to be equal to the rate in anaerobic growth (Alsiyabi et al., 2021). Furthermore, arbitrary uptake rates were set for p-coumarate and oxygen since the actual uptake rates are not known. However, the general observed trend in the trade-off plot should remain the same.

2.8. Statistical methods

Data points for growth curves and GC-MS data represent the averages
of biological triplicates, and error bars are the calculated standard deviation from raw data based on the population. Independent, two-tailed t tests were used to calculate statistical significance at a 95% confidence interval ($\alpha = 0.05$), and the $p$ value is listed where appropriate.

3. Results and discussion

Our recent efforts suggested granule formation is a limiting factor for maximum production of PHBV by R. palustris due to one large granule predominately being formed inside the cells (Alsiyabi et al., 2021). PhaP1 leads to smaller and more abundant PHB granules in C. necator, and it was hypothesized that expression of phaP1 would increase overall PHBV monomer titer from R. palustris. Thus, phaP1 was expressed in R. palustris with the aim of overproducing PHBV from lignocellulosic sources by maximizing the use of intracellular space via producing smaller and more abundant granules.

3.1. Gene expression analysis for phaP1

Gene expression analysis was first conducted via RT-PCR to verify the expression of phaP1 in the phaP1 strain compared to the wild type strain. Fig. 1 depicts the expression bands for phaP1 and 16S rRNA in each condition. All conditions showed significant expression of the 16S rRNA housekeeping gene. Furthermore, all conditions for the phaP1 strain yielded expression of phaP1, whereas the wild type strain did not. In Fig 1A, the positive and negative controls using R. palustris gDNA did not yield expression, which was to be expected since phaP1 is naturally occurring in C. necator. In Fig. 1B, the controls for 16S rRNA using C. necator gDNA did not yield expression since this occurs naturally in R. palustris.

3.2. Comparisons of growth and PHBV production

Analyses were conducted to assess the impacts on growth and production of PHBV monomers due to phaP1 expression in R. palustris. First, we conducted growth comparison analyses for both aerobic and anaerobic environments to decipher if growth was impacted by expression of phaP1. Fig. 2 depicts the logarithmic growth curves of strains containing the backbone plasmid with phaP1 inserted (phaP1), the backbone without phaP1 (backbone plasmid), and the wild type (WT) strains. Under anaerobic conditions, there was no significant difference in maximum OD between the wild type and phaP1 strains ($p = 0.395$). There was also no significant difference in maximum OD between the wild type, phaP1, and backbone plasmid strains in aerobic conditions ($p > 0.05$). Hence, expression of phaP1 did not yield significant changes in the maximum OD in neither anaerobic nor aerobic conditions. However, the phaP1 strain yielded a slower growth rate in aerobic conditions compared to the wild type strain. Later, we discuss how we explore this further with the application of genome-scale metabolic modeling.

We then assessed changes in 3HV and 3HB production due to phaP1 expression based on our hypothesis that phaP1 expression would enhance production. Under anaerobic conditions, there was no statistical significance in maximum titers (i.e. 3HB + 3HV fractions) between the wild type and phaP1 strains ($p = 0.137$), but there was a significant difference in 3HV fractions between the strains (Fig. 3A). The phaP1 strain generated a significantly higher 3HV fraction (0.25 g/L) compared to the wild type strain (0.04 g/L) under anaerobic conditions ($p = 0.00316$). Expression of phaP1 fostered 3HB and 3HB production from R. palustris aerobically, which does not occur in the wild type strain (Fig. 3B). Total production from the phaP1 strain in aerobic conditions (0.7 g/L) was significantly higher than the maximum anaerobic titer (0.41 g/L) for the wild-type strain ($p = 1.8 \times 10^{-5}$). The 3HV fraction generated aerobically from the phaP1 strain (0.074 g/L) was also significantly higher than the wild type fraction (0.04 g/L) in anaerobic conditions ($p = 0.000126$). The backbone plasmid strain was used as a control under aerobic conditions to decipher if phaP1 expression yielded significantly higher 3HB and 3HV production compared to the backbone alone. The backbone plasmid strain produced a relatively small amount of 3HB (approximately 0.05 g/L maximum), which was merely 1/14 that of the production from the phaP1 strain (0.7 g/L). Furthermore, the backbone plasmid strain did not yield any 3HV production, compared to 0.074 g/L generated from the phaP1 strain. Statistical comparison of the 3HB ($p = 1.243 \times 10^{-6}$) and 3HV ($p = 5.402 \times 10^{-3}$) fractions produced from the backbone plasmid versus the phaP1 strains is significant, which supports the hypothesis that aerobic PHBV production is significantly higher with phaP1 expression compared to the backbone plasmid alone.

Once the growth and PHBV monomer fraction production analyses had been conducted, we wanted to further assess why the phaP1 strain yielded a slower growth rate than wild type under aerobic conditions. It was hypothesized that the reduced growth rate could be due to tradeoffs between biomass and PHBV production. A genome-scale metabolic model of R. palustris, called iRpa940, was recently applied to compare tradeoffs in growth and PHBV production from a variety of substrates including p-coumarate (Alsiyabi et al., 2021). Genome-scale modeling synergizes results from the context of whole-cell metabolism, utilizing annotated breakdown pathways for the corresponding substrates. Since there was a lack of kinetic parameters and concentration ranges for PHBV production reactions in R. palustris, only tradeoffs corresponding to PHB were assessed previously. However, it is likely that the outcomes utilizing the model are very comparable between PHB and PHBV since the monomer products are produced by the same enzymes. Thus, this genome-scale metabolic model was employed here to assess the hypothesis that the phaP1 strain had a reduced growth rate due to the new PHBV production compared to wild type R. palustris (Alsiyabi et al., 2019, 2021). A plot comparing PHB and biomass production for the phaP1 strain under aerobic conditions was generating via flux balance analysis simulations with iRpa940 utilizing p-coumarate as the substrate (Fig. 3C). As expected, the relationship between growth rate and PHBV production is linear and reflects a direct negative correlation. Thus, since the phaP1 strain produced 3HB and 3HV under aerobic conditions compared to no production from the wild type strain, the phaP1 strain had a lower growth rate to compensate for the production.

In summary, expression of phaP1 yielded increased 3HV fractions under both anaerobic and aerobic conditions, and fostered PHBV monomer production aerobically compared to no measurable aerobic production by the wild type strain. Increased 3HV fractions are desirable since they create a bioplastic with increased tensile strength, impact strength, and flexibility that render it more applicable in a wider array of applications (Heinrich et al., 2015). Our recent efforts identified several key metabolic factors impacting PHB production by R. palustris under anaerobic conditions (utilizing the Calvin Benson Bassham cycle as an electron sink), including a significant thermodynamic bottleneck for the thiolase reaction (phaA) as well as a significant dependence of the reductase reaction (phaB) on the NADPH/NADP ratio, and reductase will likely be rate-limiting regardless of metabolic conditions due to low catalytic efficiency (Alsiyabi et al., 2021). Increased production of 3HV is linked to increased propionyl-CoA pools, whereby 3-ketothiolase conducts condensation of acetyl-coenzyme A (acetyl-CoA) and propionyl-CoA to form 3HV. Thus, it is hypothesized that expression of phaP1 enables more efficient utilization of propionyl-CoA pools that fostered higher 3HV fractions (Mezzina et al., 2017). Due to the constitutive expression of PHB producing enzymes (Alsiyabi et al., 2021), the increased utilization efficiency of propionyl-CoA enabled by phaP1 results in a higher rate of 3HV production. Under aerobic conditions, the presence of a highly electrophilic electron acceptor (oxygen) means that the wild type’s propionyl-CoA utilization efficiency is not sufficient to shuttle electrons.
away from oxygen into 3HV, which explains why phaP1 overexpression is required for 3HV production under such conditions. Although the expression of phaP1 did not yield higher 3HB production compared to the wild type strain, the 3HV fraction was higher and ultimately yields a bioplastic with more desirable thermomechanical properties compared to PHB alone (Li et al., 2016). Hence, heterologous phasin expression in R. palustris could be a strategy for producing bioplastics that have improved market applicability via altering the monomer fractions of the polymer as shown in other organisms (Kawashima et al., 2015).

However, the mechanism for the fostered aerobic production due to phaP1 expression is more elusive and will require more investigation in the future. Wild type R. palustris produces PHBV anaerobically via photoheterotrophy whereby it uses light as an energy source to pump protons out of the cell to maintain redox balance that allows ATP synthase to proceed (Larimer et al., 2004). Although R. palustris obtains energy from light under photoheterotrophy it must be supplemented with more carbon than carbon dioxide alone. We found in our recent efforts that the choice of substrate significantly impacts PHBV accumulation, and that utilizing more reduced substrates like p-coumarate fosters more PHBV accumulation compared to less reduced substrates like acetate (Alsiyabi et al., 2021). Under aerobic conditions (chemoheterotrophy), a proton motive force is built by releasing protons from the cell via an electron transport chain, and ATP synthases use protons to form ATP from ADP. In other words, glycolysis, β-oxidation of free fatty acids, and the TCA cycle generate reducing equivalents under aerobic conditions. Thus, there is not as much of a need to formulate PHBV under aerobic conditions due to the innate differences in redox balances for the metabolisms. Interestingly, expression of phaP1 in R. palustris fostered PHBV production aerobically compared to no measurable PHBV production by the wild type strain. PhaP1 performs a large role in the stability and mobilization of PHB inclusions in C. necator in which a PhaP1-negative mutant renders PHB autodegradation, so this granule stability could be one mechanism that fostered aerobic production in R. palustris (Kuchta et al., 2007). Additionally, altering the surface to volume ratios of granules is one proposed indirect effect phasins have regarding interactions of phasins with PHB depolymerases. Since many granule-associated-proteins are constitutively expressed in both C. necator and R. palustris (e.g. PHB synthases and depolymerases), changes in phasin expression has been shown to have a large impact on PHB production due to interactions with these proteins (Kuchta et al., 2007). Another plausible cause for the aerobic production due to the expression of phaP1 is that PhaP1 is strictly regulated by PhAR.
at the transcription level in *C. necator* in which PhaP1 production is based on the amount of PHB in cells and the presence of PhaC synthase, and heterogenous expression in *R. palustris* might not have this regulatory mechanism (Maestro and Sanz, 2017; Potter et al., 2002; York et al., 2002). Thus, more effort is needed to identify the mechanisms behind PhaP1 in this heterogenous system with *R. palustris*, and in particular in aerobic environments. In the end, engineering the production of PHBV aerobically by *R. palustris* boosts the industrial production potential since it provides flexibility for industrial processing.

Ultimately, *R. palustris* is a very metabolically robust bacterium with the ability to convert sustainable feedstocks (e.g. lignin) into several value-added products (PHBV, hydrogen, n-butanol). This makes *R. palustris* an attractive candidate for engineering toward industrial production, and through this study we further enhance *R. palustris’* PHBV production via expression of *phaP1* (Phasin 1) from the model bacterium *C. necator*. There are several routes for further engineering this system, which include improving the 3HV fractions under aerobic conditions by assessing tradeoffs between the methyl citric acid cycle and the propionate pathway (Steinbüchel and Lütke-Eversloh, 2003), creating other synthetic systems that incorporate more of the PHB chassis from *C. necator* or other organisms, and also by further characterizing and engineering *R. palustris’* native PHBV production chassis (e.g. phasins employed by *R. palustris*). After exploring changes in gene expression, growth, and PHBV monomer production due to the expression of *phaP1*, we next conducted TEM to decipher if expression indeed fostered changes in granule formation in *R. palustris*.

### 3.3. Changes in PHBV granule formation

In addition to the gene expression, growth, and PHBV production analyses, TEM was conducted to test the hypothesis that expression of *phaP1* in *R. palustris* would boost PHBV production by fostering smaller and more abundant granules. Fig. 4 depicts the TEM images of wild type cells (in the left column) versus *phaP1* cells (in the right column). Fig. 4A and B of the wild type and *phaP1* cells respectively in anaerobic conditions shows a discrepancy from the large, single granule produced in the wild type cells compared to smaller, and more numerous granules in the *phaP1* cells. There are some variations in terms of brightness between the PHBV granules, which can be attributed to the small granules getting replaced by embedding medium easier than the larger ones as well as variations in section thickness (Wahl et al., 2012). Furthermore, expression of *phaP1* appears to alter the subcellular localization of the PHBV granules in *R. palustris*, which has been shown in *C. necator* as well (Wahl et al., 2012). The granules in the cells from the *phaP1* strain are more dispersed inside the cells rather than remaining primarily at the poles. There is also a clear discrepancy between images taken of cells grown under aerobic conditions (Fig. 4C-F). Wild type *R. palustris* grown aerobically did not yield any PHBV titer, which is reflected in the lack of granules inside the cells (Fig. 4C, E). Expression of *phaP1* fostered PHBV production aerobically, which is supported by the granule formation observed in Fig. 4D, F. Ultimately, TEM analysis supports the hypothesis that expression of *phaP1* would foster changes in granule formation inside the cells, which also likely contributes to the altered PHBV production capabilities in each condition.

### 4. Conclusions

In this study the Phap1 phasin from *C. necator* was expressed in *R. palustris* to overproduce PHBV by creating smaller and more abundant granules and optimizing the use of intracellular space. Expression of *phaP1* yielded PHBV production from *R. palustris* aerobically (0.7 g/L), which does not occur in wild type, and to a significantly higher titer compared to wild type anaerobic production (0.41 g/L). The 3HV fractions were also significantly increased under both anaerobic and aerobic conditions. Thus, heterologous phasin expression in *R. palustris* provides flexibility for industrial processing and fosters compositional changes in copolymers with better thermomechanical properties compared to PHB alone.
