Abstract

Background: Regular physical activity (PA) can prevent many non-communicable diseases, such as cardiovascular disease (CVD) and diabetes mellitus (DM). The present study aimed to assess the health benefits of physical activities including blood pressure and comorbid conditions.

Methodology: This is a prospective cohort case-control study that recruited 300 Saudi volunteers living in the city of Hail, Northern Saudi Arabia.

Results: Out of 300 participants 155(51.7%) were males and 145 (48.3%) were females. There were 111(37%) participants committed to regular physical activity and the remaining 189(63%) without a defined commitment to physical activity (Uncommitted). Among 111 persons who claimed a commitment to regular physical activity (committed), 61(55%) were males and 50(45%) were females. The majority of committed individuals were at the age group 21-25 years followed by age group 26-30 and 31-35 years representing 32, 30, and 20 persons, respectively. The physical activity was highly practiced at the age range 21-30 years and this was found to be statistically significant \( P < 0.001 \).

Conclusion: There is a low prevalence of physical activity in Hail region, particularly among females, which necessitates the suggestion of appropriate awareness programs. Younger and elder populations are in much need to be targeted with PA awareness programs.

Introduction:

Physical activity (PA) and regular exercise have countless health benefits; almost everybody can feel the benefit from becoming physically more active. A goal of 150 min/week of moderate-to-vigorous intensity PA was recommended as most international guidelines for beneficial PA. These recommendations indicated that this intensity of PA is the minimum needed to gain health benefit [1].

Different concepts have been employed to define the individual physical activity, such as, "PA," "exercise," and "physical fitness". Though these terms appear to be confusing, repeatedly used interchangeably. The term "PA" is ascribing any bodily movement made by skeletal muscles that consumes energy (measured in kilocalories). There
are many forms of PA in daily life, such as occupational, sports, conditioning, household, or other activities. Exercise is a type of PA that is planned, structured, and repetitive and has the objective of improvement or maintenance of physical fitness. Physical fitness is a set of qualities that are either health- or skill-related, which can be measured with specific tests [2]. The evidence is overwhelming with risk drops of at least 20%-30% for more than 25 chronic medical conditions and premature mortality. Even higher risk reductions (ie, ≥ 50%) are perceived when objective measures of physical fitness are engaged. International PA guidelines usually endorse 150 minutes per week of moderate- to vigorous-intensity PA [3]. Exercises and PA promotion according to public health recommendations for PA enhanced cardiovascular (CV) fitness, muscle strength and PA performance [4].

As exercise is acknowledged to enhance CV consequences such as angiogenesis and endothelial function, much consideration is being assumed to exercise to recover the number and function of circulating angiogenic cells (CACs). Consequently, there is a rising body of evidence that acute, short-term, and chronic exercise have a beneficial influence on the number and function of diverse subgroups of CACs [5]. Exercise in young adults has been steadily revealed to enhance many characteristics of physiological and psychological health with tremendous realizing of the potential benefits of exercise with the proceeding of age. Precisely, exercise improves cardiovascular, musculoskeletal, and metabolic health through diminutions in oxidative stress, chronic low-grade inflammation and modulating cellular processes within a range of tissues [6].

In spite of well-known evidence that PA is efficient for tumbling the risk of non-communicable diseases, as well as the significance and cost-effectiveness of PA counseling in the primary care setting, few studies have been conducted regarding PA counseling in Saudi Arabia [7]. Thus the present study aimed to assess the health benefits of physical activities including blood pressure and comorbid conditions.

Materials and Methods:-
This is a prospective cohort case-control study that recruited 300 Saudi volunteers living in the city of Hail, Northern Saudi Arabia. Participants were targeted in different public settings in the city. Participants were randomly selected by simple random method regardless of age, gender, education level or occupation. A purposeful questionnaire was designed and used for obtaining the necessary data. Beside demographical data of the participants, the poll included variables, such as, period of commitment to physical activity, daily duration of physical activity, lifestyle-related factors including: stress factors, energy drinks, coffee consumption, smoking, sleeping hours per day, daily sleeping time; comorbid conditions including: diabetes mellitus (DM), hypertension, chronic kidney disease, and high blood cholesterol.

Study population
The study population was grouped based on the physical activity levels and divided into two groups: physically active committed group (ascertained as committed) and uncommitted group (ascertained as uncommitted). “Committed group” was defined as people who were committed to regular physical activity (exercise) for at least 6 months. “Uncommitted group” included those who were not involved in any regular exercise but might be involved in leisure time activities.

Blood pressure and heart rate measurements
Resting heart rate & Blood pressure measurements were taken after 5 minutes rest in a seated position in a quiet place. The measurements were evaluated using an oscillometric device (beurer BM58).

Data Analysis
Statistical Package for Social Sciences (version 23) was used for analysis and to perform the Pearson Chi-square test for statistical significance (P-value). The 95% confidence level and confidence intervals were used. A p value less than 0.05 was considered statistically significant.

Ethical Consent
Each participant was asked to sign a written ethical consent during the questionnaire’s interview.

Results:-
This study assessed the benefit of physical activity in 300 volunteers, their ages ranging from 18 to 64 years old with a mean age of 27 years. Out of 300 participants, 155(51.7%) were males and 145 (48.3%) were females. There were
111 (37%) participants committed to regular physical activity and the remaining 189 (63%) without a defined commitment to physical activity. Among 111 persons who claimed a commitment to regular physical activity (committed), 61 (55%) were males and 50 (45%) were females. The majority of committed individuals were at the age group 21-25 years followed by age group 26-30 and 31-35 years representing 32, 30, and 20 persons, respectively. The physical activity was highly practiced at the age range 21-30 years and this was found to be statistically significant \( P < 0.001 \).

The highest levels of physical activities were noticed among higher educated people, graduated and secondary levels representing 82 and 25 persons in this order, as indicated in Table 1, Fig 1.

**Table 1:** Physical activity by sex, age, and education

| Variable | Committed (n=111) | Uncommitted (n=189) | Total (n=300) |
|----------|-------------------|---------------------|---------------|
| Sex      |                   |                     |               |
| Males    | 61                | 94                  | 155           |
| Females  | 50                | 95                  | 145           |
| Total    | 111               | 189                 | 300           |
| Age      |                   |                     |               |
| ≤20 years| 10                | 31                  | 41            |
| 21-25    | 32                | 85                  | 117           |
| 26-30    | 30                | 32                  | 62            |
| 31-35    | 20                | 18                  | 38            |

**Figure 1:** Physical activity by sex, age, and education

Out of the 111 committed persons, 37, 26, and 20 were found to practice physical activity for periods of 13-24 months, 6 months and more than 25 months, correspondently, as shown in Fig 2. About 68, and 41 persons practice physical activity for 21-30 and 11-20 days per month, as shown in Fig 3.
Most study subjects use to practice physical activity for < 60 minutes per day, followed by 91-120 minutes constituting 37 and 36 subjects in this order as shown in Fig 4.

With regard to the cardiac systolic efficiency, 136/300(45.3%) were found with optimal systolic blood pressure (50/111(45%) committed and 86/189(45.5%) were uncommitted). Hypertension was indicated in 33/300(11%) participants (9/111(8%) committed and 24/189(12.7%) were uncommitted). With regard to the cardiac diastolic efficiency, 112/300(37.3%) were found with optimal systolic blood pressure (43/111(39%) committed and 69/189(36.5%) were uncommitted). Hypertension was indicated in 56/300(18.7%) participants (17/111(15.3%) committed and 39/189(20.6%) were uncommitted). About 264/300(88%) of the study subjects were found with heart rates between 60 and 100 per minute. Rate levels over 100 were identified among 29/300(10%) (4/111(3.6%) were committed and 25/189(13.2%) were uncommitted), as indicated in table 2, Fig 5.

![Figure 4: Duration (minutes) of physical activity per day](image3)

### Table 2: Heart efficiency by physical activity

| Variable       | Committed (n=111) | Uncommitted (n=189) | Total(n=300) |
|----------------|-------------------|---------------------|--------------|
| **Systolic blood pressure** |                   |                     |              |
| Optimal        | 50                | 86                  | 136          |
| Normal         | 31                | 48                  | 79           |
| High-normal    | 21                | 31                  | 52           |
| Hypertensive   | 9                 | 24                  | 33           |
| **Diastolic blood pressure** |                   |                     |              |
| Optimal        | 43                | 69                  | 112          |
Table 3, summarizing physical activity status by lifestyle cardiovascular related factors. Stress was commonly encountered at work 79/300(26.3%) (31/111(28%) were committed and 48/189(25.4%) were uncommitted). Within entire groups; stress factors were more common among the committed group. Energy drinks consumption was noted among 15/111(13.5%) of the committed compared to 49/189(26%) of the uncommitted. Coffee consumption was noted among 97/111(87.5%) of the committed compared to 154/189(81.5%) of the uncommitted. Smoking habit was noted among 31/111(28%) of the committed compared to 28/189(15%) of the uncommitted. Around 12/111(11%) of the committed used to sleep for less than 6 hours per day compared to 27/189(14.3%) of the uncommitted. Late sleeping habit after 12:00 PM was identified among 53/111(47.7%) of the committed compared to 102/189(54%) of the uncommitted, as indicated in Table 3.

As it was shown in Fig 6, the frequencies of comorbid conditions were lower in the committed group compared to the uncommitted group

Table 3:-Physical activity by cardiovascular related factors

| Variable            | Committed (n=111) | Uncommitted (n=189) | Total (n=300) |
|---------------------|-------------------|---------------------|--------------|
| Stress factors      |                   |                     |              |
| At work             | 31                | 48                  | 79           |
| At home             | 25                | 12                  | 37           |
| At community        | 9                 | 18                  | 27           |
| More than 2 factors | 16                | 9                   | 25           |
| Others              | 0                 | 2                   | 2            |

| After 12:00 AM | 53  | 102  | 155 |

Figure 6: Physical activity by comorbid conditions

**Discussion:**

With the increase in the sedentary lifestyle in recent years, many diseases including DM, hypertension, and CVD are becoming highly prevalent among the physically inactive population. Accordingly, the current study aimed to assess the value of physical activity in enhancing cardiac parameters, as well as, decreasing the comorbidities such as DM, hypertension etc.

The present study indicated a prevalence of physical activity of 37% among the studied population, which is a very low level. In Study from Saudi Arabia to determine prevalence and pattern of leisure time physical activity among adult Saudis aged 18-65 years, only 21.0% of the included sample were considered as being sufficiently active and 10.4% were in the high active category with beneficial health effects [8]. Compared to the results of this study, these findings may indicate the improvement in PA status in recent years in Saudi Arabia, which necessitate the importance of awareness in such population. Another Saudi study involved the extent of physical activity among physicians and assessing the likelihood of counseling the patients on physical activities. About 65.2% of respondents were doing moderate to vigorous physical exercise and 34.8% of them were physically inactive [9].

In the present study, males were more active than females and the majority of the active persons were found at the age range 21 to 30 years. These findings call for educational work in children, adolescents, and older people. Moreover, the highest levels of physical activities were noticed among higher educated people.
Most of the study subjects were found to practice physical activity for periods of less than one year. However, this period might not be enough to produce apparent benefits, particularly with low intensity. Moreover, most study subjects use to practice physical activity for < 60 minutes per day. These findings may emphasize the narrow gaps among the studied two groups (committed and uncommitted).

With regard to the cardiac parameters (systolic, diastolic pressure, and heartbeat), showed no differences between the two investigated groups. These might be attributed to the short period and low activity intensity, which was indicated for the majority of studied persons. Intended outcomes may require strict inclusion and exclusion criteria in term of duration and intensity of physical activity. Fixing 6 months as inclusion period regardless of PA intensity and cycle extension might be a limitation in the present study.

As lifestyle-related factors such as stress [10], smoking [11], caffeine [12], and sleeping quality [13] can produce cardiovascular changes, the present study considered them and revealed no statistically significant. Although the random distribution of these factors was relatively similar amongst both groups (committed and uncommitted), there were no apparent variations.

In the present study, the overall frequencies of comorbid conditions were lower among active individuals (committed) compared to relatively inactive persons (uncommitted). It was reported that Leisure-time physical activity may be considered as an efficient and inexpensive non-pharmacological tool for DM treatment [14]. Exercise is an effective strategy for reducing blood pressure in the general population; however, it is not known whether exercise would have a comparable benefit in people with moderate to advanced chronic kidney disease and hypertension [15]. Recent studies showed that exercise and lifestyle risk factor management are critical for the secondary prevention of cardiovascular disease but are poorly adhered to [16]. Elevated levels of high-density lipoprotein cholesterol (HDL-C) have been associated with a decreased risk of coronary heart disease (CHD). An active lifestyle is necessary in order to improve lipid HDL-C, including (but not limited to) physical exercise [17].

In conclusion:--
there is a low prevalence of physical activity in Saudi Arabia, particularly among females, which necessitates the suggestion of appropriate awareness programs. Younger and elder populations are in much need to be targeted with PA awareness programs. Further studies with strict inclusion and exclusion criterion needed to assess the health benefits variations between active and inactive individuals.
