Introduction — Majorana fermions realized as vortex core bound states of superconducting condensates have been attracting considerable interest in connection with the application to quantum computation.[1–3] Such vortices obey the non-Abelian statistics,[4–9] and because of this distinct feature, they are utilized as decoherence-free qubits. The realization of Majorana bound states has been discussed for the quantum Hall effect systems,[4,7] p + ip superconductors,[7–11] superconductor-topological-insulator interfaces,[12,13] and s-wave Rashba superconductors.[14–16] The origin of Majorana fermions acting as non-Abelian anyons is intimately related to the existence of the non-Abelian topological order, which yields the fractionalization of quasiparticles.[17–18] Generally, topological order is characterized by a nontrivial topological number associated with the global structure of the Hilbert space, and hence, the existence of a nonzero energy gap which separates the topological ground state and non-topological excited states stabilizes the topological order.

In this paper, we propose an example of systems realizing Majorana fermions, which is unusual in the above-mentioned sense of topological stability, but ubiquitous in real materials: Majorana fermion states may be realized in large classes of noncentrosymmetric (NCS) superconductors such as CePt$_3$Si, CeRhSi$_3$, CeIrSi$_3$, Li$_2$Pt$_3$B, are known to possess superconducting gap-nodes.[19–22] In these systems, some of time-reversal invariant $k$-points reside close to the Fermi level.[24] Our finding indicates that if the total number of these $k$-points is odd, and the superconducting gap vanishes (or, at least, becomes sufficiently small) at these points, stable Majorana fermion modes appear under applied magnetic fields. We expect that such Majorana fermion states may be realized in large classes of NCS superconductor with gap-nodes.

Majorana fermions in edges and in a vortex core — To be concrete, we consider a two-dimensional $d$-wave superconductor with the Rashba spin-orbit (SO) interaction, though the following argument is basically applicable to any NCS nodal superconductors. The Hamiltonian is given by $H = \frac{1}{2} \sum_k \psi_k^\dagger \mathcal{H}(k) \psi_k$, with

$$\mathcal{H}(k) = \begin{pmatrix}
\epsilon_k - h \sigma_x + g_k \cdot \sigma & i \Delta_k \sigma_y \\
-i \Delta_k \sigma_y & -\epsilon_k + h \sigma_z + g_k \cdot \sigma^* \nend{pmatrix}, \quad (1)$$

where $\psi_k^\dagger = (c_{k\uparrow}^\dagger, c_{k\downarrow}^\dagger, c_{-k\uparrow}^\dagger, c_{-k\downarrow}^\dagger)$, $\epsilon_k = -2t(cosk_x + cosk_y) - \mu$, $g_k = 2\lambda(sin k_y, -sin k_x, 0)$, $k = (k_x, k_y)$, and $\sigma = (\sigma_x, \sigma_y, \sigma_z)$ the Pauli matrices. $h = \mu_B H_z$ is a Zeeman magnetic field. The gap function is the $d_{x^2−y^2}$-wave type, $\Delta_k = \Delta_0(cos k_x - cos k_y)$, or the $d_{xy}$-wave type, $\Delta_k = \Delta_0 sin k_x sin k_y$. We neglect the orbital effect of the magnetic field for a while since it does not change our results qualitatively, as long as $H_z < H_c2$.

We, first, demonstrate that there is a gapless chiral Majorana fermion mode on the edge of the system. For this purpose, we numerically calculate the energy spectrum of the system with the open boundary condition imposed for the $x$-axis, and the periodic boundary condition for the $y$-axis. The results are shown in FIG. In the case of the $d_{x^2−y^2}$-wave pairing, when the condition $-4t - \mu < h < -\mu$ is satisfied, a gapless edge mode...
appears for \( k_y \sim 0 \). (FIGII(A)) Note that this edge mode is isolated from continuum of gapless excitations from the gap nodes with the finite Fermi momentum. Because of the particle-hole symmetry of the Hamiltonian, the existence of one zero energy mode implies that the zero energy edge mode for \( k_y \sim 0 \) is a Majorana fermion. The above condition implies that when the Fermi level crosses \( k \)-points close to time-reversal invariant points in the Brillouin zone in the absence of the magnetic field, say, the \( \Gamma \) point; i.e. \( \mu = -4t \), the Majorana edge mode appears for any nonzero \( H_z \) below \( H_{c2} \). This property makes a sharp contrast to the \( s \)-wave pairing state considered in refs.[14–16], for which a large magnetic field appears for any nonzero \( H \). Generally, impurity scattering affects the superconducting state with gap-nodes. We consider only the case that the density of impurities is sufficiently small so that the superconducting gap is not much reduced. As will be shown later, there is indeed a topological protection mechanism in spite of the existence of bulk gapless excitations. Before discussing the topological mechanism, however, we here present a heuristic argument on this issue to grasp an intuitive physical picture. Generally, impurity scattering affects the superconducting state with gap-nodes. We consider only the case that the density of impurities is sufficiently small so that the superconducting gap is not much reduced.

The existence of the chiral Majorana fermion mode implies that there is a Majorana fermion mode in a vortex core of the superconducting condensate when the vorticity \( n \) is odd. In the case of the \( d \)-wave pairing, the analysis of the vortex core state is cumbersome, in contrast to the \( s \)-wave pairing or the \( p + ip \)-wave pairing states, since the gap function of the \( d \)-wave state is not an eigen state of the orbital angular momentum, and, moreover, there is no truly localized bound state in a vortex core because of interactions with delocalized nodal excitations[25, 26]. However, as in the case of the \( s \)-wave Rashba superconductor[14, 27], we can construct the Majorana zero energy mode from quasiparticles with \( k \sim 0 \) at least in some parameter regions. The eigen function for this zero energy state is \( \phi^T = (u_\uparrow, u_\downarrow, u_\uparrow^*, u_\downarrow^*) \) with \( u_\uparrow = ie^{i\pi n\lambda}f(r) \), \( u_\downarrow = -ie^{i\pi n\lambda}f(r) \) and \( f(r) = \sqrt{\frac{h}{\pi \lambda_r}}e^{-\frac{r}{\lambda_r}} \) for large \( r \). Here \( n \) is odd. In the \( d \)-wave pairing state, in addition to this zero energy mode, there are four gapless extended states outside of the vortex core which stem from the four gap-nodes[25, 26]. Since the total number of the zero energy mode is odd, one Majorana mode survives. Thus, we have a zero energy Majorana fermion mode in the vortex core.

**Stability of Majorana fermions** — The next important question is whether Majorana fermions found above are stable or not against weak perturbations such as impurities even in the presence of gapless nodal excitations. As will be shown later, there is indeed a topological protection mechanism in spite of the existence of bulk gapless excitations. Before discussing the topological mechanism, however, we here present a heuristic argument on this issue to grasp an intuitive physical picture. Generally, impurity scattering affects the superconducting state with gap-nodes. We consider only the case that the density of impurities is sufficiently small so that the superconducting gap is not much reduced. We, first, consider the case of the \( d_{x^2−y^2} \)-wave pairing. In a semi-infinite system with an open boundary, there is only one chiral Majorana edge mode, while there are four gapless modes which stem from four nodes of the \( d_{x^2−y^2} \)-wave superconducting gap. To generate an energy gap in the Majorana spectrum, we need even numbers of Majorana modes which are paired into complex fermions. Thus, for this geometry, the chiral Majorana edge mode is stable against interactions with nodal excitations, and also against impurity scattering. However, this argument is not applicable to the case with two open boundaries at the opposite sides of the system. In this case, two counter-propagating chiral Majorana modes reside in the two opposite edges, as depicted in FIGsII(C). Interactions between bulk gapless nodal excitations and

![FIG. 1: Energy spectra for systems with open boundaries for the x-direction and the periodic boundary condition for the y-direction. \( \mu = -4t \), \( \lambda = 0.5t \), \( \Delta_\theta = t \) and \( h = 2t \). (A) (B) \( d_{x^2−y^2} \)-wave pairing. (D) (E) \( d_{xy} \)-wave pairing. The distance between two edges is \( L = 90 \) [(A) (D)] and \( L = 30 \) [(B) (E)]. In (A) and (D), chiral gapless edge modes at \( x = 0 \) and \( x = L \) are depicted, respectively, in green and red curves. (C) (F) Chiral edge modes counter-propagating on two opposite edges for \( d_{x^2−y^2} \)-wave pairing (C) and \( d_{xy} \)-wave pairing (F).](image-url)
two chiral Majorana modes may give rise to long-range tunneling between two Majorana modes. We note that such long-range tunneling via nodal excitations does not occur in a clean system, because of the mismatch of the Fermi momenta of nodal excitations $k_F \neq 0$ and that of the chiral Majorana modes with which $k_F \sim 0$ for the $d_{x^2-y^2}$-wave pairing. When there are impurity potentials, a Majorana mode and nodal excitations on an edge can be hybridized via impurity scattering, leading to the long-range tunneling of the Majorana fermions in two opposite edges: $H_{\text{tun}} = t(r_0 - r_0')\gamma(0, y_0)\gamma(L, y_0')$, where $\gamma(x, y)$ is a Majorana fermion operator, $r_0 = (0, y_0)$ and $r_0' = (L, y_0')$ are the positions of impurities and the tunneling amplitude $t(r_0 - r_0') \sim 1/|r_0 - r_0'|$ for a large $|r_0 - r_0'|$. We introduce a complex fermion operator, $\alpha(y) = \frac{1}{2}[\gamma(0, y) + i\gamma(L, -y + y_0 + y_0')]$. Then, the Hamiltonian for two chiral Majorana edge states can be rewritten into that of the 1D chiral Dirac fermion, $H_{\text{redge}} = -iv \int dy \alpha(y)\partial_y \alpha(y)$. The long-range tunneling term is also expressed as $H_{\text{tun}} = t_0(2\alpha(y_0)\alpha(y_0) - 1)$. Because of the chiral character of the Dirac fermion $\alpha$, this tunneling term raises only forward scattering, the effect of which is merely to shift the chemical potential. As a result, the chiral Dirac fermion is still gapless. Going back to the Majorana fields, we conclude that the two chiral Majorana edge modes are stable against sufficiently dilute impurities. In contrast, in the case of the $d_{x^2-y^2}$-wave pairing, the long-range tunneling via nodal excitations exists even in the absence of impurities, as depicted in FIG.1(F). In this case, an energy gap opens around $k_y \sim 0$, and the Majorana mode disappears even for a relatively large value of $L$, for which the Majorana mode still exists for the $d_{x^2-y^2}$ wave pairing. (see FIGs.1(B) and (E))

We, now, consider the stability of the Majorana mode in a vortex core. In addition to the localized zero energy Majorana solution, there are also delocalized states caused by gapless nodal excitations with the finite Fermi momenta. When there are multiple vortices in the system under consideration, these delocalized states raise long-range tunneling between spatially separated vortices, which may destroy the zero energy Majorana mode. In the system with odd numbers of vortices, one Majorana mode in a vortex core survives. However, in the case with even numbers of vortices, the Majorana mode disappears unless they are separated enough from each other.

Topological order and topological protection of Majorana fermions — The above consideration strongly implies that there is a topological order which ensures the stability of Majorana fermion modes even for nodal superconductors with bulk gapless excitations. However, in sharp contrast to a gapful topological order, the bulk Chern number $\nu_{\text{Ch}}$ is not well-defined for our gapless system. Nevertheless, we clarify here that the parity of the Chern number $(-1)^{\nu_{\text{Ch}}}$ is well-defined even for nodal superconductors. The parity of the Chern number ensures the stability of the topological order in our system.

Let us first try to define the Chern number in our gapless system. The simplest way to do this is to introduce a small perturbation eliminating all nodes (i.e. gapless points) in the spectrum. For instance, adding a small $id_{xy}$ term in the gap function, we can easily remove all the nodes in our $d_{x^2-y^2}$ superconductor. After removing the nodal points, the Chern number can be evaluated in the standard manner. This procedure, however, does not work well after all. The problem is that the value of the Chern number depends on the perturbation we choose. As a result, one can not have a unique definition of the Chern number for gapless systems.

On the other hand, we find that this procedure does define the parity of the Chern number uniquely. From the particle-hole symmetry, the parity of the Chern number is recast into

$$(-1)^{\nu_{\text{Ch}}} = \text{exp} \left[ i \int_{\Gamma_1} dk_i A_i(k) + i \int_{\Gamma_3} dk_i A_i(k) \right],$$

where $A_i(k)$ is the “gauge field” defined by the bulk band wave function $|u_n(k)\rangle$, $A_i(k) = \sum_n (u_n(k)\partial_k u_n(k))$, and $\Gamma_i$ is the time-reversal invariant $k$-points, $\Gamma_{i=1,2,3,4} = (0, 0), (\pi, 0), (0, \pi), (\pi, \pi)$. Then, for the Hamiltonian (1), we can show that

$$(-1)^{\nu_{\text{Ch}}} = \prod_{i=1,2,3,4} \text{sgn}[\epsilon_i^2 + \Delta_i^2 - \hbar^2],$$

irrespective of the perturbation (such as $id_{xy}$ term) we choose. This means that we have a unique value of the parity in the limit of $id_{xy} \rightarrow 0$; i.e. the parity of the Chern number $(-1)^{\nu_{\text{Ch}}}$ is well-defined even for nodal superconductors, although the Chern number $\nu_{\text{Ch}}$ itself is not. The parity of the Chern number characterizes the topological phase in nodal superconductors. For $(-1)^{\nu_{\text{Ch}}} = -1$, there exists an odd number of topologically stable Majorana fermions in the edges and in a vortex core for nodal superconductors. For example, for the model (1) with $-4\mu - \mu < h < -\mu$, we obtain $(-1)^{\nu_{\text{Ch}}} = -1$ from (3). Thus, the existence of the gapless Majorana edge mode in FIG.1 is characterized by the odd parity $(-1)^{\nu_{\text{Ch}}} = -1$. On the other hand, for $(-1)^{\nu_{\text{Ch}}} = 1$, there is no topologically stable Majorana fermion. We emphasize that the formula (3) is applicable only to systems with particle-hole symmetry, and thus, the topological order in gapless systems is specific to topological superconducting states.

In addition to the parity of the Chern number, one can consider another topological number dubbed 1D $Z_2$ invariant [31]. The 1D $Z_2$ invariant $(-1)^{\nu^{[C_{ij}]}}$ is introduced as a line integral along a specific time-reversal invariant path $C_{ij}$ passing through $\Gamma_i$ and $\Gamma_j$. In a similar manner above, it is shown that the 1D $Z_2$ invariant is well-defined even for our nodal superconductor, and we
obtain $(-1)^{v[C_{ij}]} = \text{sgn}[(\Delta^2_{ij} + \mu^2)] \cdot \text{sgn}[\Delta^2_{ij} - \mu^2]$. For the model \( C \) with 4 \( t < h < -\mu \), this formula yields $(-1)^{v[C_{ij}]} = -1$ for both \( d_{x^2-y^2} \) and \( d_{xy} \) superconductors. From the bulk-edge correspondence, this \( Z_2 \) invariant determines the location of the Majorana edge fermions at \( k_y \sim 0 \), as illustrated in FIGs.\( A, B \), and (D). Since the 1D \( Z_2 \) invariant is associated with a local structure in the Brillouin zone, its non-triviality does not directly lead to the topological stability. However, the 1D \( Z_2 \) invariant is useful for identifying the location of zero energy Majorana edge modes, as shown above. On the other hand, the odd parity of the Chern number introduced above definitely characterizes the global nontrivial topology of the Hilbert space, ensuring the topological protection mechanism of Majorana modes.

The above consideration can be straightforwardly generalized to a general multi-band nodal superconductor. In this case, when the superconducting gap vanishes or becomes sufficiently small at the time-reversal invariant \( k \)-points \( \Gamma \), the parity of the Chern number is evaluated as $(-1)^{v[\text{ch}]} = \prod_{\alpha=1,2,3,4} \text{sgn}[\mathcal{E}_\alpha(k)]$, where \( \mathcal{E}_\alpha(k) \) is the normal dispersion of the superconductor. The index \( \alpha \) specifies an energy band including the spin degrees of freedom. Therefore, when the Fermi level is located close to odd numbers of time-reversal invariant \( k \)-points, and the superconducting gap vanishes at these points because of the symmetry requirement, the NCS nodal superconductor possesses topologically protected Majorana fermion modes under an applied small magnetic field.

**Experimental detection of Majorana fermions —** For the experimental detection of Majorana fermions in nodal superconductors, one promising approach is to exploit an interferometry measurement proposed for a superconductor-topological-insulator junction in refs.\[34,35\]. We consider a setup similar to those proposals, but with a difference that, instead of a superconductor-topological-insulator junction, a bulk \( d \)-wave Rashba superconductor is used. The contribution from nodal excitations to the conductance in the \( d \)-wave pairing state vanishes like \( \sim T \) at sufficiently low temperatures, and thus, the current is dominated by that carried by two Majorana edge modes. The dependence of the conductance on the parity of vorticity inside the superconductor signifies clearly the Majorana fermion contributions.\[31,33\]

The non-Abelian nodal superconductor considered here is also realizable in an interface between a centrosymmetric nodal superconductor such as High-\( T_c \) cuprates and a semiconductor, as considered in the case of the \( s \)-wave pairing state by Sau et al. and Alicea\[13,16\]. In such a system, because of the considerably large superconducting gap, the experimental detection of Majorana modes may be easier.

**Summary** — We have demonstrated that even in nodal superconductors such as the \( d \)-wave pairing state, Majorana fermion modes, which are topologically protected against weak perturbations and lead to the non-Abelian statistics, are realized under a certain realistic condition, in spite of the existence of bulk gapless nodal excitations. Our results establish a concept of a gapless topological phase, and open the possibility of detecting Majorana fermions in various NCS superconductors with gap-nodes found in real materials.
