Abstract Mars possesses dynamical features called polar vortices: regions of cold, isolated air over the poles circumscribed by powerful westerly jets which can act as barriers to transport to dust, water, and chemical species. The 2018 Global Dust Storm was observed by multiple orbiters and offered a valuable opportunity to study the effects of such a storm on polar dynamics. To this end, we assimilate data from the Mars Climate Sounder and Atmospheric Chemistry Suite into a Mars Global Climate Model. We find that the storm had asymmetrical hemispherical impacts, with the northern vortex remaining relatively robust while the southern vortex was substantially diminished in its intensity. We propose that this asymmetry was due both to the storm's latitudinal extent, as it extended further south than north, and to its equinoctial timing, occurring as the southern vortex was already decaying. We show that both polar vortices, in particular the northern, were reduced in ellipticity by the storm. There was a well-correlated reduction in stationary topographic wave activity at high latitudes in both hemispheres. We demonstrate that the characteristic elliptical Martian polar vortex shape is the pattern of the stationary waves, which was suppressed by the shifting of the polar jet away from regions of high mechanical forcing (north) or reduction of polar jet intensity by a reduced meridional temperature gradient (south). These asymmetric effects suggest increased transport into the southern (but not northern) polar region during global dust storms at northern autumn equinox, and more longitudinally symmetric transport around both poles.

1. Introduction

Mars' winter atmosphere is characterized by a polar vortex of low temperatures around the winter pole, circumscribed by a strong westerly jet (Mitchell et al., 2015; Waugh et al., 2016). These vortices are a key part of the atmospheric circulation and are heavily involved with dust and volatile transport (e.g., Holmes et al., 2017). Planetary polar vortices are a common feature of atmospheres in the Solar System, but Mars' differs from Earth's in several important respects. Among the most notable and visible is their peculiar annular structure. On Earth, the potential vorticity (PV) (a way of diagnosing the presence and strength of the polar vortex; see discussion below) of the polar vortices increases monotonically toward the pole; on
Mars, there is a distinctive ring of higher PV around the pole, then a minimum over the pole itself (Mitchell et al., 2015; Waugh et al., 2016). This annular PV structure should be barotropically unstable but appears to persist over seasonal timescales; modeling indicates that Mars' low radiative relaxation timescales can help maintain this equilibrium (Seviour et al., 2017). The current best explanation for the annular structure itself appears to be diabatic heating from CO₂ condensation over the winter pole; as the CO₂ condenses, it releases latent heat energy, warming the lower atmosphere and causing a local reduction in PV (Rostami et al., 2018; Scott et al., 2020; Toigo et al., 2017). Mars' polar vortices also show a hemispheric asymmetry, with the northern vortex being stronger in reanalyzes than the southern (Mitchell et al., 2015).

Another feature of the Martian polar vortices is their elliptical shape, particularly in the northern hemisphere (Waugh et al., 2016). It has been speculated by Mitchell et al. (2015) and Rostami et al. (2018) that this ellipticity could be linked to topography, something not incorporated into their simplified model of the Martian circulation. This elliptical shape is only visible when averaged over time periods of 10 s of sols; over smaller timescales, the polar vortex structure is less coherent and composed of smaller regions of high PV (Waugh et al., 2016). Rostami et al. (2018) attributed this to inhomogeneous deposition of condensing CO₂ ice. Meanwhile, Mitchell et al. (2015) found that the Martian polar vortices are consistently centered over the pole itself at the solstices, suggesting a relatively lesser (compared to Earth) role for wave-mean flow interactions in controlling the shape of the polar vortices.

The Martian polar vortices appear to have a complex relationship with atmospheric dust loading. Mitchell et al. (2015) found that in the Mars Analysis Correction Data Assimilation (MACDA) reanalysis, there was less seasonal variability in the polar vortex structure due to planetary Rossby wave activity (and resulting in sudden stratospheric warming), as there is on Earth; rather, any variability was linked to dust-induced changes to the Hadley circulation (and resulting intensified polar warming). Specifically, they investigated the effect of a regional dust storm at \( L_S = 320° \) in MY 26 (a “C”-type storm; see Kass et al. [2016]), and found that it acted to shift the northern vortex toward the equator by \( \sim 10° \) in latitude and weaken the vortex circulation overall. Guzewich et al. (2016) used a Mars Global Climate Model (MGCM) with an analytically prescribed dust scenario to investigate the effects of high southern hemisphere dust loading on the northern polar vortex, and vice-versa. They found that regional and global dust storm (GDS) events could produce sudden transient vortex warming, disrupting the northern polar vortex for periods of up to 10 s of sols, by shifting the downwelling branch of the cross-equatorial Hadley cell poleward. By contrast, the southern polar vortex was significantly more robust to high northern hemisphere dust loading. The exact relationship between the polar vortices and atmospheric dust content is an important one to understand, as it has implications for the transport of both volatiles and dust itself through the vortices (e.g., McCleese et al., 2017; Smith et al., 2017).

Previous studies have used reanalyzes to investigate Mars' polar vortices, but to date have only used those which assimilate Thermal Emission Spectrometer (TES) data, namely the MACDA (Mitchell et al., 2015; Waugh et al., 2016) and Ensemble Mars Atmosphere Reanalysis System (EMARS) (Waugh et al., 2016) reanalyzes. This study assimilates Mars Climate Sounder (MCS) column dust optical depth (CDOD) products and MCS and Atmospheric Chemistry Suite (ACS) temperature retrievals. MCS CDOD products are not limited, as TES CDOD nadir measurements were, to areas with relatively warm surface temperatures (>220 K) (Smith, 2004), allowing greater coverage over the seasonal CO₂ caps and therefore more CDOD data for assimilation over these regions. This study also uses the newer 2D MCS retrievals, one goal of which improved retrievals over the polar regions specifically (Kleinböhl et al., 2017). ACS temperature retrievals have the advantage of observing over different Martian local times.

Crucially for the understanding of how large-scale dust loading affects Mars' polar dynamics, this study assimilates CDOD and temperature data from the real GDS that occurred in MY 34. The MY 34 GDS was first detected at \( L_S = 186° \) and matured into a global, planet-encircling event by \( L_S = 200° \), before beginning its long decay phase around \( L_S = 213° \) and returning to climatological levels around \( L_S = 270° \) (Kass et al., 2020). At the height of the GDS, the planet-encircling dust cloud extended to approximately 45°N and 70°S, and the greatest atmospheric temperature response (at 50 Pa) was seen in the southern hemisphere, from the equator to the southern pole itself (Kass et al., 2020). GDS in general has been found to have significant impacts on Martian atmospheric dynamics (e.g., Fedorova et al., 2020; Guzewich et al., 2014; McDunn et al., 2013). The MY 34 event was observed by an unprecedented number of spacecraft, including the Mars
Reconnaissance Orbiter (MRO) and the ExoMars Trace Gas Orbiter (TGO), making it an ideal candidate for using data assimilation to investigate its impacts on polar dynamics. Previously, Guzewich et al. (2016) used a prescribed dust scenario to investigate the effects of a GDS-like event at solstice. The use of a reanalysis allows the study of a realistic GDS-level dust loading closer to equinox, affording a chance to study GDS effects at a different season. This also allows comparison with a recent study on the MY 34 GDS using MCS data directly, and its findings of significant diurnal variation in southern polar vortex structure (Kleinböhl et al., 2020). Finally, this study devotes time to investigate wave-mean flow interactions, and specifically study how the horizontal structure of the polar vortices at this season might be affected by such interactions.

2. Methods

2.1. Model

The model used for this study is an MGCM, a four-dimensional numerical model which exists as a collaborative effort between the Laboratoire de Météorologie Dynamique, the University of Oxford, the Open University, and the Instituto de Astrofísica de Andalucía (Forget et al., 1999). This version of the MGCM uses a spectral dynamical core to solve the equations of fluid motion, with a finite-difference scheme in the vertical dimension and a semi-Lagrangian scheme for tracer advection (Lewis et al., 2007). The MGCM advects dust using a two-moment scheme with a log-normal size distribution, and total CDOD is scaled at each column to match assimilated observations (Madeleine et al., 2011; Streeter, Lewis, Patel, Holmes, et al., 2020). The dust distribution in the vertical is allowed to evolve without constraint. Dust in the MGCM is radiatively active, using radiative properties derived from observations (Wolff et al., 2006, 2009). The MGCM radiative transfer scheme is reliable to within $\sim$10% error even at the very high dust loadings observed during the 2018 GDS (Streeter, Lewis, Patel, Holmes, et al., 2020; Toon et al., 1989).

2.2. Retrievals and Data Assimilation

The MGCM was run with a modified version of the Analysis Correction data assimilation scheme (Lorenc et al., 1991), tuned for use on the Martian atmosphere (Lewis et al., 1997, 2007). Orbitally retrieved temperature profiles were assimilated using the method previously used in this scheme for TES (Holmes et al., 2018; Lewis et al., 2007) and MCS (Holmes, Lewis, & Patel, 2019; Holmes, Lewis, & Patel, et al., 2019; Steele et al., 2014) data, while CDOD derived from MCS limb dust profiles was assimilated to constrain MGCM dust columns (Lewis et al., 2007). The assimilation scheme and MGCM were the same as those used for the OpenMARS reanalysis data set, which currently extends to MY 32 (Holmes, Lewis, & Patel, 2019; Holmes, Lewis, & Patel, et al., 2019).

The retrieved temperature profiles used were from MCS (McCleese et al., 2007) aboard MRO (Zurek & Smrekar, 2007) and from ACS (Korablev et al., 2018) aboard TGO. MCS temperature profiles extend to $\sim$85 km, with an intrinsic vertical resolution of $\sim$5 km (Kleinböhl et al., 2009). The sun-synchronous orbit of the MRO results in two approximately fixed local times for MCS observations, namely 0300 and 1500 at nonpolar latitudes (Zurek & Smrekar, 2007). The retrieval version used was v5.2, the latest version which incorporates two-dimensional radiative transfer to correct for lateral gradients in temperature and aerosol, resulting in improved retrievals over the poles (Kleinböhl et al., 2017). The exception was during the period of the 2018 GDS, for which a reprocessed version (v5.3.2) was used; this reprocessed version incorporated information from extra channels on MCS (Kleinböhl et al., 2020). ACS temperatures for MY 34 were also assimilated, in the form of temperature profile retrievals from solar occultations by the NIR (near-infrared) channel, with an intrinsic vertical resolution of 1–3 km and altitude range of 0–90 km depending on the TGO orbit (Fedorova et al., 2020). NIR performed on average nine occultations per Martian Sol throughout the relevant period of MY 34 (Fedorova et al., 2020). TGO’s non-sun-synchronous orbit means that ACS temperatures were available at sunrise/sunset local times, near the terminator.

Assimilated CDOD data were from MCS, which does not directly measure dust columns but provides a derived column product based on extrapolation of retrieved dust profiles. As stated above, however, while the CDOD in the MGCM was given by assimilated MCS CDOD, the vertical distribution of dust in the MGCM was allowed to evolve freely without prescription. As MCS CDOD is reported at infrared wavelengths while the MGCM uses visible wavelengths for dust radiative transfer calculations, CDOD values...
were first converted from 21.6 μm to 670 nm via a conversion factor of 7.3 (Kleinböhl et al., 2011). Dayside equatorial CDOD values were filtered out before assimilation to avoid spuriously high values (Montabone et al., 2015), except during the period of the GDS itself (Montabone et al., 2020). As with MCS temperatures, v5.2 retrievals were used except during the GDS period, when v5.3.2 retrievals were used.

2.3. Simulations Performed

A single MGCM simulation utilizing data assimilation (“reanalysis”) was performed covering multiple Mars years, which included the periods $L_s = 200°–220°$ for both MY 33 and MY 34. These periods were focused on for the purposes of this article. The reanalysis assimilated MCS and ACS temperature profiles and MCS CDOD products. The MGCM was run at a spatial-spectral resolution T42, corresponding to a spatial resolution of $\sim 3.75°$ ($\sim 215$ km at the equator), with 50 topography following vertical levels with midpoints from at shallowest $\sim 5$ m and at deepest $\sim 105$ km above the surface. The MGCM was run without water cycle parametrizations to isolate the effects of dust.

For the purposes of this article, MY 33 was chosen as a non-GDS year to compare against MY 34. MY 33 was a very typical MCS year in terms of dust loading, including in the timing and magnitude of its regional “A”-, “B”-, and “C”-storms. The very average dust loading of MY 33 allows a comparison between a situation of “normal” dust loading and a situation of GDS-scale dust loading. The $L_s = 200°–220°$ period was focused on as it represents the height of global, homogeneous dust loading during the GDS period in MY 34 (Kass et al., 2020).

2.4. Potential Vorticity Diagnostic

A diagnostic used frequently throughout this article is Ertel PV. PV is a measure of air circulation derived from the vorticity and stratification of the atmosphere, and is valuable for being conserved like a material tracer under adiabatic processes (Haynes & McIntyre, 1987), making it especially useful for the study of polar dynamics; the polar vortices can be defined as regions of high PV around the poles. PV has both dynamical components, in the vorticity of both the air mass itself and the planet, and thermodynamic elements, in the form of the potential temperature structure and static stability of the atmosphere. The PV of an air mass on an isentropic surface is conserved, and cannot be created, destroyed, or transported across isentropic surfaces (Haynes & McIntyre, 1987); therefore, a large-scale local reduction in PV implies significant mixing along the isentropic surface, associated with diabatic and/or frictional processes. PV can be defined as

$$PV = -g(\xi + f) \frac{\partial \theta}{\partial p}$$

where $g$ is the gravitational acceleration (3.72 m/s$^2$ on Mars), $\xi$ is the relative isentropic vorticity (the relative vorticity of the air mass on that particular isentropic surface, an isentropic surface being a surface of constant potential temperature), $f$ is the Coriolis parameter (the vorticity associated with the planetary rotation at a particular latitude), $\theta$ is the potential temperature, and $p$ is the pressure.

PV is given as a value on a particular isentropic surface; this study uses the 300 K isentropic surface for consistency with previous studies of the Martian polar atmosphere (e.g., Mitchell et al., 2015; Waugh et al., 2016). This corresponds to an approximate altitude range of 20–30 km, and when winds are presented in this article they are integrated between 20 and 30 km.

PV is typically positive/negative in the northern/southern hemisphere, and increases in magnitude near the poles due to the value of $f$. The term “magnitude” is used throughout this article for PV values, to make it clear that a larger negative PV value means a greater absolute value of PV. For simplicity, 1 “MPVU” (Mars potential vorticity unit) is defined throughout this article as $1 \times 10^{-4}$ K m$^2$ kg$^{-1}$ s$^{-1}$, or 100 PVU (a standard unit used for terrestrial studies).
3. Results

3.1. Diurnally Averaged Changes

This section explores the effects of the MY 34 GDS over both the north and south poles (“NP” and “SP”) as averaged over all local times.

Figure 1 shows the average structure of the NP and SP polar vortices between $L_S = 200^\circ$ and $220^\circ$ for MY 33 and MY 34, and the difference between them. NP PV saw an overall reduction (Figure 1e) up to 15 MPVU, with the greatest reduction around latitudes $60^\circ$N–$70^\circ$N, though PV actually increased slightly over the pole itself. The reduction was highly longitudinally asymmetric, with maxima in PV reduction in the eastern hemisphere at $180^\circ$E–$90^\circ$E and $-30^\circ$E to $30^\circ$E. Despite this, the gross morphology of the NP vortex (Figures 1a and 1c) showed minor changes compared to the SP. The MY 34 vortex showed reduced ellipticity compared to MY 33, and the disappearance of a local PV minimum over the pole itself.

NP zonal winds also changed, tending to increase in the GDS case up to 20 m/s (Figure 1e) north of $60^\circ$N, particularly around $90^\circ$E–$180^\circ$E, but decreasing southward of $60^\circ$N. The wind speed increases align with the PV decreases, occurring primarily in the east. In the western hemisphere, there was little change except between latitudes $70^\circ$N–$80^\circ$N, where zonal winds decreased by around 8 m/s between $-120^\circ$E and $30^\circ$E. At the lower latitudes $50^\circ$N–$60^\circ$N, in (primarily) the eastern hemisphere, zonal winds speeds decreased up to 16 m/s, showing a poleward jet shift. The GDS-induced changes were asymmetric and made the MY 34 wind structure less elliptical than in MY 33. A strong local wind maximum up to 120 m/s in the eastern hemisphere ($55^\circ$N, $60^\circ$E) in MY 33 was substantially reduced in MY 34, creating a more longitudinally symmetric jet. Despite the generally more symmetrical MY 34 wind structure, the jet appears shifted off-pole toward $-30^\circ$E. Finally, the closer clustering of contours in MY 34 shows a latitudinal narrowing of the westerly jet. There was a visible anticorrelation between PV and zonal wind speeds.

SP PV also showed an overall absolute reduction, up to 5 MPVU. The pattern of decrease (Figure 1f) correlates exactly with the MY 33 polar vortex structure (Figure 1b). The annular PV structure in MY 33 is both longitudinally asymmetric, weaker in the west/stronger in the east, and centered off-pole, with the central PV minimum around $80^\circ$S, $-30^\circ$E. The MY 34 PV structure is far more uniform; there is still a (weaker) annular pattern, centered over the pole itself, and reduced longitudinal asymmetry. The proportional decrease of PV at the SP (up to 50%) was much greater than at the NP, resulting in a drastically altered morphology and substantially reduced PV across the entire vortex, suggesting large-scale PV mixing from dynamical and/or diabatic changes. PV mixing is also implied by the fact that absolute PV increased slightly equatorward of $60^\circ$S.

SP zonal winds generally increased where PV decreased, up to 30 m/s, and decreased elsewhere (outside the vortex) by similar amounts (Figure 1f). The greatest wind increases were at the MY 33 local PV minimum (Figure 1b); this calm “eye” had very low wind speeds in MY 33. This signifies a shift of the remnant vortex from $\sim 5^\circ$ off-pole to over the pole itself. Zonal wind gradients were weaker in MY 34, showing a less coherent jet core. The decrease in zonal wind speeds equatorward of $60^\circ$S was likely due to increased dust loading reducing the meridional temperature gradient. The MY 34 wind structure was more longitudinally symmetric than in MY 33, and centered around the pole itself. Again, there was a visible anticorrelation between PV and zonal wind speeds.

The MY 34 GDS significantly boosted the mean meridional circulation (MMC), strengthening both the dominant cross-equatorial clockwise and the southern anticlockwise Hadley cells (Figure 2I–III). A stronger Hadley cell signifies greater transport of (warmer) air from lower toward higher latitudes, causing adiabatic heating. The MY 34 cross-equatorial Hadley cell also extended further poleward, indicating transport toward higher northern latitudes than under non-GDS conditions, from $\sim 60^\circ$N in MY 33 to $\sim 75^\circ$N in MY 34. This was not seen in the southern anticlockwise Hadley cell.

In addition to thermally direct circulatory cells, there is frequently a thermally indirect cell at mid-high northern latitudes. Such features at midlatitudes on Earth are called “Ferrel cells,” but are not technically real circulatory cells; rather, they indicate the presence of mechanical forcing from planetary wave activity due to thermal contrasts at mid-latitudes (Salby, 2011), and their presence in the Eulerian MMC is an artifact of the averaging process (see Andrews et al., 1987, Chapter 3). Given the thermal contrast at northern
midlatitudes at this time of year ($L_s = 200^\circ$–$220^\circ$, early northern winter), the presence of these cells implies baroclinic planetary wave activity. The weakening of the northern thermally indirect cell in MY 34 (Figure 2) indicates that the GDS suppressed baroclinic wave activity over Mars’ northern lowlands, where such activity is generally strongest (e.g., Barnes et al., 1993).

The meridional flow was altered at different longitudes, reflecting the increased longitudinal symmetry in the MY 34 polar vortex structure. Figure 2 shows meridional winds as calculated for six different longitude
Figure 2. Top row: mean meridional circulation calculated for the $L_S = 200^\circ$–$220^\circ$ period. Positive/negative values indicate clockwise/anticlockwise flow. All other rows: meridional wind averaged over different longitude ranges for the same period. Positive/negative values indicate northward/southward flow.
In MY 33, the seasonally typical large-scale flow of the MMC is replicated at some longitudes: $-180^\circ$E to $120^\circ$E and $0^\circ$E–$60^\circ$E, where the northward meridional flow extends to the NP. However, northern hemisphere southward (away from pole) flow occurs at longitudes $-120^\circ$E to $0^\circ$E and $60^\circ$E–$180^\circ$E. These correspond to northern topographic depressions (Figure S1) where baroclinic wave activity is strongest (e.g., Barnes et al., 1993). This pattern suggests a wavenumber 2 stationary wave. In the south, at $0^\circ$E–$180^\circ$E (eastern hemisphere), the southward flow extends to the SP, while in the western hemisphere there is northward flow, indicating wavenumber 1 stationary wave activity. These flow patterns correlate with the MY 33 polar vortex structure (Figures 1a and 1b). In both hemispheres, poleward flow correlates with where the vortex is compressed poleward, while equatorward flow correlates with where the vortex extends further equatorward.

The equivalent longitude ranges in MY 34 show complex changes, but some broad patterns are identifiable. In general, the flows show greater zonal symmetry than in MY 33, resembling the MMC more closely, especially at southern mid-high latitudes. In the north, the wavenumber 2-like pattern in MY 33 changes to a more dominant wavenumber 1-like pattern, with roughly half the planet showing northward meridional flow and half showing southward meridional flow. This generally more longitudinally symmetrical flow matches the more longitudinally symmetrical NP and SP polar vortices (Figures 1c and 1d). In the eastern hemisphere, where there is southward flow extending to the SP in MY 33, in MY 34, this is significantly weakened. Likewise, in the west, where there is flow away from the SP in MY 33, in MY 34, this is diminished and/or reversed. This altered flow matches the highly symmetric MY 34 SP vortex (Figure 1d). In the north, the MY 34 meridional flow pattern generally shows northward flow toward the NP between longitudes $-60^\circ$E to $120^\circ$E, and southward flow away from the NP between longitudes $120^\circ$E and $-60^\circ$E. This GDS flow pattern therefore implies an MY 34 NP vortex which is compressed poleward between $-60^\circ$E and $120^\circ$E, but extends further equatorward between $120^\circ$E and $-60^\circ$E. Examination of Figure 1c shows that the highest PV values can be found on the $120^\circ$E and $-60^\circ$E side of the planet; for example, the same $\sim35$ MPVU contour which extends to $70^\circ$N at $-150^\circ$E extends to only $80^\circ$N at $30^\circ$E.

It has been shown that the longitudinal asymmetries in the polar vortices are related to longitudinally asymmetric meridional wind patterns, but what is the cause of this longitudinal asymmetry? Figure 3 shows the meridional wind deviation integrated between altitudes 20 and 30 km for $L_S = 200^\circ$–$220^\circ$ for (top) MY 33, (middle) MY 34, and (bottom) the difference between MY 34 and MY 33. Red (blue) in the bottom plot corresponds to either increased (decreased) northward meridional wind deviation or decreased (increased) southward meridional wind deviation.
to −120° E, and a southward flow between approximately −110° E to −10° E and 70°E–160° E. There is also stationary wave activity at southern high latitudes indicating a wavenumber 2 feature at midlatitudes which transitions into a wavenumber 1 feature poleward of 75°S–80°S; other modeling work suggests that this becomes a more unambiguous wavenumber 1 at southern winter (Hollingsworth & Barnes, 1996). There is a northward flow between approximately −70°E and 10° E, and a southward flow between approximately 90°E and 180°E, both extending all the way to the pole. There are also flows at southern mid-latitudes: a north-to-south flow between approximately −20°E and 60° E, and a less well-defined south-to-north flow between approximately 60°E–120° E.

The MY 34 GDS drastically changed stationary wave structures (Figures 3b and 3c); northern amplitudes were decreased up to 20 m/s. There remained two significant remnants: southward flow around −110°E and −10°E, and adjacent northward flow around −10°E to 70° E. These remnant flows were also constrained to poleward of ∼45° N. The other two flows were almost completely destroyed, creating a wavenumber 1-like pattern. In the south, the mid-high latitude wavenumber 2 structure was completely destroyed, leaving only a weakened wavenumber 1 feature consisting of weak northward flow between −180°E and 60° E and weak southward flow between 60°E and 180° E.

These stationary wave structures and changes match the polar vortex structures and changes. In the north, the MY 33 wavenumber 2 pattern matches the longitudinal asymmetry of the elliptical polar vortex (Figure 1a). The elongated parts of the ellipse are where the meridional wind deviation consists of southward flow, roughly between −110°E to −10° E and 70°E–160° E. The narrow parts of the ellipse are where the meridional wind deviation consists of northward flow, roughly between −10°E to 70° E and 170°E to −110° E. The MY 34 GDS significantly diminished northern stationary wave amplitudes, particularly between −180°E to −120° E and 70°E–180° E. This correlates well with the longitudes of greatest PV reduction (Figure 1e). Where the pre-existing stationary wave structure remained relatively intact, such as −120°E to −60° E, PV changes were minimal.

Likewise in the south, equatorward vortex extension matches where the meridional wind deviation consists of northward flow, between −70°E and 10° E. Where the vortex is more constrained toward the pole is where the meridional wind deviation consists of southward flow, between 10°E and 180°E. The MY 34 GDS almost completely destroyed southern stationary wave activity (Figure 3b), matching the highly symmetrical MY 34 vortex (Figure 1d). The greatest change occurred where the MY 33 stationary wave amplitudes were greatest, between −60°E and 60° E; this is where the MY 33 vortex was most latitudinally extended.

While the NP PV structure was largely unaltered during the GDS except becoming more longitudinally symmetric and less annular, the SP polar vortex saw a proportionally much greater and more extensive PV reduction, even at latitudes where the stationary planetary wave pattern was not significantly altered; this suggests that in addition to dynamics, other factors contributed to the SP vortex morphological changes. Figure 4 shows zonally averaged temperatures and dust opacities for MY 33 and MY 34. It is apparent that GDS-induced atmospheric heating at southern high latitudes was much greater (up to 33 K at 20–30 km) than at northern high latitudes (up to 15 K at 20–30 km, and significantly less within the vortex). The southern diurnally averaged vortex saw significant diminishment, while the northern diurnally averaged polar vortex narrowed in latitudinal extent but remained coherent and clearly defined. Crucially for the SP thermal winds, the southern hemisphere meridional temperature gradient was substantially reduced except nearest the pole, visible in the increased spacing between vertical contour lines. This matches with the GDS-induced increase in dust opacity, which occurred primarily between latitudes 75°S and 50°N (Figure 4f), though there was also a large increase (up to 0.02) between 60°S and 90° S up to 20 km. There was little increase in dust opacity north of 60°N (<0.01), and any increase occurred below ~10 km. This implies that diabatic heating from the increased dust presence may have had a role in affecting the SP but not NP vortex.

The plots of zonally averaged dust opacity (Figures 4b, 4d, and 4f) also indicate differences in tracer transport into the polar vortices from the non-GDS and GDS cases. There was a slight increase in dust opacity below 10 km around 65° N, but a slight decrease further north around 75°N–80° N. In the south, there was a greater dust opacity increase, up to 0.02 between 5 and 15 km, with smaller increases up to 30 km. This indicates minimal (if any) dust transport into the more coherent northern vortex, and possibly greater dust
exclusion from the vortex itself (which could lead to increased opacities on the vortex boundary). In the south, by contrast, dust opacity increased up to 30% at around 10 km and up to 65% around 30 km (where absolute opacities are lower). The results suggest enhanced MY 34 tracer transport into the southern vortex, while the northern vortex remained a coherent transport barrier.

To better ascertain the roles of diabatic and adiabatic/dynamical heating, shortwave (SW), longwave (LW), and net (SW + LW) atmospheric radiative heating rates were calculated, and their difference between MY 33 and MY 34 (Figure 5). SW heating relies solely on the atmospheric dust presence, while LW heating is dependent on dust and atmospheric emission. Given the Martian atmosphere's short radiative timescales, SW and LW heating rates should be in approximate balance in a radiative-convective model (except in the

Figure 4. Zonally averaged (left) temperatures and (right) dust opacities averaged between $L_s = 200^\circ$ and $220^\circ$ for (top) MY 33, (middle) MY 34, and (bottom) the difference between MY 34 and MY 33. The plotted dust opacities in subplots (b) and (d) are $\log_{10}$ values; those in subplot (f) are actual dust opacities. All dust opacities are at 670 nm, as used in the MGCM. Altitude was cropped to 50 km for the plots.
boundary layer); in a model containing dynamical processes, deviations from radiative balance indicate the presence of dynamical heating/cooling (Wolff et al., 2017). For example, in MY 33 dynamical cooling is visible between 0°S and 60°S at 10–30 km, showing the upwelling Hadley cell branches, while dynamical heating is visible at high altitudes between 30°N–60°N and 60°S–90°S, showing the downwelling Hadley cells and Mars’ characteristic polar warming (e.g., McDunn et al., 2013; Wilson, 1997).

Figure 5. Zonally averaged (top) shortwave (SW), (middle) longwave (LW), and (bottom) net (SW + LW) radiative heating rates averaged between \( L_s = 200° \) and 220° for (left) MY 33, (middle) MY 34, and (right) the difference between MY 34 and MY 33. Altitude was cropped to 50 km for the plots.
The increased dust loading in MY 34 caused increases in both SW heating and LW cooling rates, particularly between latitudes 75°S and 45°N. Southern SW heating rates increased south to 75°S and up to 30 km altitude by at a minimum of 6 K/sol (Figure 5c), indicating the important role of direct dust-related atmospheric heating at southern high latitudes. This heating helped reduce the meridional temperature gradient at southern high latitudes, weakening the thermal polar jet and thus reducing relative vorticity, causing local PV reduction via Equation 1. This local PV reduction implies equatorward PV mixing, visible in the small absolute PV increase equatorward of 60°S (Figure 1f) as well as, in the presence of diabatic processes like diabatic descent, destruction of isentropic PV (Hoskins et al., 1985). PV destruction at higher latitudes has been estimated to occur on timescales of ∼5 sols around solstice (Barnes & Haberle, 1996), though this is likely shorter under significant diabatic heating (e.g., sunlight, dust diabatic heating, and CO₂ condensation) and could be much longer during polar night given estimated air ages there of up to 300 sols (Waugh et al., 2019). In the north, by contrast, there was a minimal alteration to SW heating rates poleward of 45°N, due to the absence of dust. Dynamical heating was also altered by the GDS: there was an increase in polar warming at both the NP and SP due to the enhanced Hadley circulation, indicated by the increase in LW cooling rates (Figures 5f and 5i). The increased dynamical heating over the SP occurred primarily above 30 km, though there was also a ∼10 K/sol increase between 20 and 30 km at 65°S. In the north, the increased dynamical heating narrowed the size of the polar vortex, but did not cause large-scale local PV reduction as in the south.

The results from analysis of atmospheric temperatures, dust opacities, and radiative heating rates suggest that the GDS induced significant dynamical changes at both poles, but also impacted the SP alone through increased diabatic heating. The effect in the north was to narrow the latitudinal extent of the polar vortex and make the polar vortex structure less elliptical and more longitudinally symmetric, but local PV reduction in the vortex was relatively minimal. The effect in the south, by contrast, was both to create a more symmetrical polar vortex and also to significantly reduce PV across the entire pole by reduction of the polar jet through atmospheric heating, leading to a much diminished diurnally averaged SP vortex.

3.2. Diurnal Behavior

This section investigates how each polar vortex was affected by the GDS at different local times. As well as the NP/SP notation described above, this section also employs the concept of Mars Universal Time (MUT). MUT is the local time at longitude 0°, for example, MUT 00:00 is when it is midnight at longitude 0°, midday at longitude 180°, and so on. Note that the MGCM uses Mars hours and minutes, of which there are the same number in a Martian sol as there are SI hours and minutes in a terrestrial day; seconds are SI seconds.

The SP vortex exhibited a high degree of diurnal variation. This behavior was first noted in MCS temperature and dust extinction profile observations from MCS by Kleinböhl et al. (2020): a mass of colder, more isolated air (indicated by higher PV) and depletion of dust (indicated by lower dust amounts, in particular at higher altitudes) following the planet’s nightside, centered around MUT 06:00. This is reproduced in the reanalysis (Figures 6g–6l): the higher absolute PV mass is centered at MUT 06:00, and followed around by a corresponding CDOD minimum (<0.6). Interestingly, there appears to be diurnal variation in the magnitude of the high PV mass, with its absolute PV being greater at MUT 02:00 and 14:00 than at 06:00 and 18:00. This asymmetry suggests that there may still be longitudinally asymmetric processes at work, despite almost complete destruction of the southern high-latitude wavenumber 1 feature (Section 3.1).

Kleinböhl et al. (2020) attribute the diurnal behavior of the SP vortex during the GDS to the variation of the MMC throughout the day, with the GDS-enhanced circulation amplifying a pre-existing pattern. To argue for this point, they present the MY 34 MMC as calculated for different local time ranges in an MGCM, with the spatial dust distribution set using a diurnally averaged MY 34 CDOD map (Montabone et al., 2020). They show a daytime circulation that transports air to the SP, and a nighttime circulation that transports air away from it, exhibiting diurnal tidal variations and explaining the presence of dust and warmer air (expressed as lower absolute PV) on the SP dayside.

The MMC at different local times was calculated for MY 33 and MY 34 (Figure S2), to see if the described pattern holds under non-GDS conditions. The MY 34 results show very good agreement with Kleinböhl et al. (2020): a strong nighttime circulation away from the SP (MUTs 02:00, 22:00), a strong daytime
circulation toward the SP (MUTs 10:00, 14:00), and a weaker dawn/dusk transitional circulation toward the SP (MUTs 06:00, 18:00). This day-night pattern also agrees well with the MY 34 EMARS reanalysis, which shows a boosted daytime poleward circulation and nighttime equatorward circulation early during the GDS (Gillespie et al., 2020). The presence of a (weak) circulation toward the SP at dawn/dusk explains why the PV minimum covers a small longitudinal extent. The MY 33 circulation closely resembles MY 34, but weaker. One would therefore expect a similar effect in MY 33: a higher absolute PV air mass, and a CDOD minimum, following Mars’ nightside. The distinctive annular shape of the vortex is maintained throughout, including the central eye location around 80° S, −60° E (Figure 6). However, there is also definite diurnal variation in PV and CDOD, with a localized increase in absolute PV following the nightside. The magnitude of this increase is highly longitudinally asymmetric: the PV minimum is over three MPVU greater at mid-night at longitude 0° (Figure 6a) than longitude 180° (Figure 6d), likely due to stationary wave influence. There also appears to be a CDOD minimum following MUT ~06:00 (Figures 6b, 6d, 6e, and 6f). These
results corroborate the Kleinböhl et al. (2020) finding that the observed MY 34 SP vortex behavior is due to an enhanced MMC boosting an already present mechanism by which warmer, dustier air is transported to the dayside of the pole and colder, clearer air remains on the nightside. As well as the local time effect, there is also a complex interplay with southern stationary waves.

Finally, given the weaker northern circulation at this season, one would expect a similar but weaker diurnal cycle at the NP vortex. Figure S3 shows some diurnal variation in the PV maximum's longitude, roughly following the nightside, but it is less clear than in the south, and more dominated by apparent intrinsic longitudinal asymmetries. PV is consistently high, up to 50 MPVU, around longitudes $-60^\circ$E to $0^\circ$E for half the diurnal cycle, and around longitudes $150^\circ$E to $-150^\circ$E for the other half; elsewhere, it is notably weaker even during local nighttime (e.g., MUT 02:00). This pattern is consistent with the observed residually elliptical PV structure visible in the diurnally averaged plot (Figure 1c). There is also an apparent minimum in CDOD diurnal variation following the PV maximum, as at the SP. Again, the pattern is less obvious than in the south. These results suggest local time variations at the NP similar to those in the SP, but largely obscured by planetary wave effects.

4. Discussion

The MY 34 GDS had a significant effect on the morphology of both the southern and northern polar vortices, through both altered dynamics (in the north) and a combination of altered dynamics and altered radiative heating (in the south). For both hemispheres, the change in the dynamics came in the form of changes to the meridional flow, linked to changes to the high latitude stationary wave structure. This stationary wave structure is an alternative interpretation of the morphology of both polar vortices at this time of year, with the northern wavenumber 2 feature following the NP vortex's characteristic elliptical shape. These are two possible perspectives, wave-based or PV-based, on the same phenomenon.

The GDS-induced changes to the stationary waves were reflected in changes in the shape of polar vortices, specifically reducing their longitudinal and, in the southern case, latitudinal asymmetry. Indeed, the amplitude changes in the northern hemisphere wavenumber 1 feature exactly correlate to modeled changes in PV. In the south, the GDS-induced changes to the heating rates in the atmosphere also had a crucial effect on the diurnally averaged polar vortex structure. Increased atmospheric heating from the high southern dust loading in conjunction with dynamical heating reduced the meridional temperature gradient, substantially reducing the strength of the polar jet and causing large-scale PV mixing and dilution along the isentropic surface. The remnant westerly jet was shifted to a tighter area circumscribing the pole. This was a dramatic acceleration of the already ongoing decay of the SP vortex. In the north, by contrast, there were minimal changes in radiative heating rates at high latitudes, preserving the strength of the polar vortex even as its area and ellipticity decreased by the (longitudinally asymmetric) expansion of the Hadley cell to higher latitudes.

The effect of the GDS on northern stationary wave activity was twofold. Most relevant for the polar vortex, one effect was to shift the latitude of the NP jet northwards, away from the high amplitude zonal topography of the northern mid-latitudes, which mechanically forces the wavenumber 2 stationary wave (Nayvelt et al., 1997), thereby reducing high latitude stationary wave activity associated with the polar jet. There was residual ellipticity in the MY 34 NP vortex, visible in the zonal wind and PV structure in Figure 1c and in remnant stationary wave activity between $-90^\circ$E and $60^\circ$E, which can be likely attributed to the presence of high-latitude topographic gradients north of Alba Patera and in Acidalia Planitia. Second, at lower, sub-45°N latitudes, where differential heating due to zonal topographic gradients play a greater role in driving stationary wave activity (Nayvelt et al., 1997), the high dust loading of the GDS dramatically reduced zonal surface temperature gradients (Streeter, Lewis, Patel, Holmes, et al., 2020), thereby dramatically reducing stationary wave activity across all longitudes. This latter effect was less relevant for the high-latitude polar vortex. At southern high-latitudes, the already weak (relative to the north) stationary wave activity was substantially reduced as well. South of $60^\circ$S, where the dust cloud extended, the reduced meridional thermal gradient reduced zonal wind speeds, decreasing mechanical forcing and the wavenumber 1 stationary wave.

The stationary wave interpretation explains not only the elliptical polar vortex shape, but why the elliptical shape is more prevalent in the northern hemisphere, as noted by Waugh et al. (2016). The non-GDS
northern hemisphere has, at the $L_S = 200°−220°$ period, a strong and latitudinally extended wavenumber 2 feature. The southern hemisphere, by contrast, has a more ambiguous stationary wave structure at this time, with a mid-high latitude wavenumber 2 feature transitioning to a wavenumber 1 feature near the pole. These wave features most likely have a topographically induced origin, both through mechanical forcing and differential heating (e.g., Haberle et al., 2019; Hollingsworth & Barnes, 1996; Nayvelt et al., 1997). Mitchell et al. (2015) and Rostami et al. (2018) hypothesized that the elliptical polar vortex shape might be linked to large-scale topography; here, we provide compelling evidence that the elliptical shape of the vortices is the shape of the stationary planetary waves, by showing that the suppression of one entails the suppression of the other.

There was some apparent disagreement with previous literature on the effects of high dust loading on polar vortex structure, though this may be due to the time of year under consideration, among other factors. Mitchell et al. (2015), using the MACDA reanalysis, found that a regional-scale dust storm at $L_S = 320°$ caused a $\sim 10°$ latitude shift in the NP vortex, as well as an overall weakening in PV. This study shows little change in the broad morphology of the NP vortex even from the very high dust loading of a GDS, and only a localized weakening in PV. A couple of factors could be responsible for this disagreement. First, and likely most importantly, the times of year are different. At $L_S = 320°$, the NP vortex is already weakening as the planet approaches equinox, while in the $L_S = 200°−220°$ period, the NP vortex is strengthening as the planet approaches northern winter solstice. While a proper intercomparison between this reanalysis and MACDA is called for, this suggests that seasonal differences could be crucial in determining polar vortex response to sudden high dust loadings. The second factor is the nature of the regional storm in question itself, and specifically its spatial location. This could have an impact on its resultant dynamical and radiative effects.

Guzewich et al. (2014) investigated the impact of the MY 25 GDS on stationary waves, primarily the wavenumber 1 mode, finding that this mode was enhanced at both northern and southern high latitudes. The results presented here are consistent with Guzewich et al. (2014) for the northern hemisphere, as they show a marked decrease in amplitude of the wavenumber 2 mode and a transition toward a more apparently dominant wavenumber 1 mode; this is even more marked at higher altitudes than those shown here. The picture in the southern hemisphere is more complex, however, as these results show decreased wavenumber 1 activity, even higher than 20–30 km (not shown). This is puzzling due to the close similarity in season and general structure between the MY 25 and MY 34 GDS, and further study is required to explain this difference.

Guzewich et al. (2016) found that the NP vortex was significantly disrupted in an MGCM with a prescribed high-dust peak at $L_S = 270°$, but not with a dust peak of standard magnitude at $L_S = 200°$. Reversing the seasonal dust loading did not impact the SP vortex. In the study presented here, the SP vortex was disproportionately affected by an equinoctial/early perihelion season GDS, when the NP/SP vortices are strengthening/weakening, respectively. This is not inconsistent with Guzewich et al. (2016), as they investigated the effects of high dust loading at southern summer solstice, $L_S = 270°$, and standard dust loading at other times of year. Comparing the two sets of results suggests a key role for seasonality of high dust loading in resultant polar vortex behavior. Given that GDS has been observed to occur at various times within the dusty season $L_S = 180°–360°$ (Shirley, 2015), with the three most recent events occurring at equinox (MY 25), solstice (MY 28), and equinox (MY 34), it is worth investigating both equinoctial and solstitial events and the likely significant effect of GDS seasonality.

At this point, it should be noted that despite the evidence of wave-related effects on the SP vortex structure, wave structure alone is not the whole story in explaining its broad morphology. Notably, planetary wave structure does not explain the off-pole presence of the eye of lower absolute PV. Following the hypothesis that the central absolute PV minimum is the result of localized diabatic heating from latent heat release as CO$_2$ condensation occurs over the pole (Rostami et al., 2018; Toigo et al., 2017), one would expect that this location in the reanalysis—approximately $80°$ S, $−60°$ E—undergoes greater CO$_2$ condensation than the surrounding seasonal cap. The reanalysis and the MCS surface CO$_2$ ice observations from Piqueux et al. (2015) offer an opportunity to try to further validate this hypothesis. MCS observations from this period show a clear ice remnant present between $70°$ S–$90°$ S and $−120°$ E to $60°$ E, even as the ice in the opposite hemisphere has almost completely disappeared (Piqueux et al., 2015). While the reanalysis shows a greater latitudinal extent of CO$_2$ ice coverage than the observations, it does agree with the observations regarding where
the most CO$_2$ ice mass is located, at the same latitude range noted earlier. The location of this remnant surface ice feature agrees very well with the location of the low absolute PV eye seen in, for example, Figure 1b.

MCS observations suggest that this location is indeed an area of greater CO$_2$ condensation, resulting in a thicker and therefore longer-lasting ice cap; alternatively, it could be that this region is colder than the surrounding areas, thereby promoting greater CO$_2$ condensation and less rapid sublimation. These “cold spots” could also be linked to the presence of CO$_2$ ice clouds (Hayne et al., 2012), and are an ongoing area of study. In any case, this would seem to be further supporting evidence for the Toigo et al. (2017) hypothesis for the cause of the annular PV structure. However, Figure 6 appears to show that the local PV minimum or “eye” has lower absolute PV during local daytime. This is contrary to what might be expected if CO$_2$ condensation was the driving mechanism behind the eye, as condensation would be expected to occur preferentially at local night due to lower atmospheric temperatures. Indeed despite low local radiative flux, the interconnectedness of the global thermal tide can still force large diurnal atmospheric variations even at high latitudes (Lee et al., 2009). One way to account for this would be to consider the diurnal pattern of mass transport (Figure S2); air mass is transported toward the south pole during the daytime, thereby supplying more mass for condensation onto the seasonal cap. This may outweigh diurnal changes in radiative flux and atmospheric temperature causing sublimation/condensation, which will be low at such high latitudes. This remains to be investigated in the future study. Finally, it is interesting to note that the GDS appears to shift the local PV minimum toward the pole itself, at least for the $L_s = 200^\circ$–$220^\circ$ period; this shows that the GDS affects whatever mechanisms are responsible for location of the off-pole eye in non-GDS conditions.

Finally, analysis of local time variations in the SP vortex during the GDS reproduces the Kleinböhl et al. (2020) results of an isolated (high absolute PV), dust-clear air mass trapped on the nightside. This study provides further evidence that the proposed mechanism, a boosting of the meridional circulation in MY 34 intensifying an existing local time pattern of nightside transport away from the SP and dayside transport toward, is indeed correct. This pattern is shown to exist at the same time period in MY 33, with a weaker but still visible impact on the diurnal variation of PV and CDOD. The weaker meridional circulation and stronger stationary wave activity mean that the diurnally averaged structure, consisting of an off-pole eye of lower absolute PV with a surrounding annulus of higher PV, remains visible at all local times. There is some diurnal variation in PV at the NP in MY 34, but this is much weaker than in the south.

5. Conclusions

The GDS had a significant impact on both the northern and southern polar vortices. In the north, the polar vortex structure (reflected via PV and zonal wind speeds) became less elliptical and more longitudinally symmetric. PV increased slightly at the pole itself and decreased at lower latitudes, indicating a narrowing of the area of the polar vortex as the Hadley cell descending branch extended further poleward. In the south, there was significant mixing and therefore local reduction of PV across the entire polar vortex, and a corresponding increase in near-pole wind speeds and decrease in wind speeds at lower latitudes. The remaining diurnally averaged polar vortex was significantly more symmetric than in the non-GDS case, and centered at the pole itself rather than off-pole. The non-GDS asymmetries in polar vortex shape at both poles were found to be linked to a longitudinally asymmetric meridional flow, reflected in the stationary planetary wave structure in each hemisphere. The GDS significantly reduced the amplitude of the northern wave-number 1 feature and almost entirely destroyed the southern stationary wave feature, which was expressed in more symmetrical polar vortices.

The MY 34 GDS also caused a peculiar feature at the southern pole: a mass of colder, isolated air coupled with a minimum in dust that followed the nightside of the planet, first seen in direct MCS observations (Kleinböhl et al., 2020). This feature was clearly visible in the reanalysis and its suggested causal mechanism, a boosted MMC enhancing a pre-existing (non-GDS) pattern of nighttime air transport away from the southern pole and daytime air transport toward it, further corroborated. This pattern was shown to be present at the northern pole in a weaker form, and at the southern pole, albeit in a weaker form, in the non-GDS year MY 33.

The intensity and shape of the polar vortices and their corresponding westerly zonal jets control what can be transported above and onto the poles themselves. The non-GDS shape and GDS-induced alteration of
the vortices therefore have potentially important consequences for both seasonal and long-term transport of dust, water, and chemical species into the polar regions and onto the seasonal CO₂ caps. The substantially diminished diurnally averaged southern vortex during an equinoctial GDS should provide a weaker barrier to transport into the southern polar region and onto the surface, while the relatively robust northern vortex should remain an effective barrier to transport. This is especially relevant considering the boosted meridional circulation during GDS. Additionally, if the poleward shift of the westerly jets is a consistent effect of equinoctial GDS, this implies that quantities such as dust, water, and chemical species can be transported to higher latitudes during these intense dust events. If this kind of pattern holds over the course of the thousands of years that Mars maintains its particular axial obliquity, this has further implications for the record of deposited dust at the southern and northern polar layered deposits, for example, as measured by the SHARAD subsurface radar (Seu et al., 2018). Over long timescales, the spatially anchored morphology of the polar vortices may influence the longitudinal pattern of dust deposition over the polar regions.

Validation is an important consideration for results from a meteorological reanalysis, particularly when based on fields (PV, wind speeds) not directly measured from orbit. The most valuable possible future measurements would be of atmospheric winds from an orbiter. These would allow better constraints on the structure of the polar vortices, and (combined with temperature measurements) direct calculation of PV. In the near future, ongoing retrievals of temperature, dust, and long-lived trace gases from TGO and its NOMAD (Patel et al., 2017; Vandaele et al., 2015) and ACS (Korablev et al., 2015, 2018) spectrometer suites will enable further investigation of tracer transport and an opportunity to cross-validate and jointly assimilate multiple orbiter observations. NOMAD/ACS provide the crucial feature of observing over a range of Martian local times, enabling exploration of the diurnal cycles of tracer transport and polar dynamics.

Data Availability Statement
Scientific color maps are from Crameri (2020). CODMAC Level 2 ACS data are available on the ESA PSA at https://archives.esac.esa.int/psa/#TableView/ACS=instrument; see Fedorova et al. (2020) for details on the retrieval technique. CODMAC Level 5 MCS retrievals (v5) are publicly available on NASA’s PDS at https://atmos.nmsu.edu/data_and_services/airmasses_data/MARS/mcs.html. Reanalysis data used in this article are publicly available on the ORDO repository (Streeter, Lewis, Patel, & Holmes, 2020). The authors thank the Editor and two anonymous reviewers for their constructive comments which have helped to improve this manuscript.
