Key Words
Endogenous endophthalmitis · Electroretinogram · Vitrectomy · Gram-positive coccus

Abstract
Background: Endogenous endophthalmitis is a rare disease and its visual prognosis is poor.
Case Reports: We present two patients, a 60-year-old man and a 53-year-old man, who developed endogenous endophthalmitis caused by Gram-positive organisms but recovered good vision after antibiotics and vitrectomy.
Results: The first patient complained of ocular pain and visual decrease in his right eye. Ophthalmoscopy showed inflammation in the anterior chamber and vitreous opacities. Antibiotic was administrated systemically, and blood culture detected Streptococcus anginosus. He underwent successful heart surgery for endocarditis and total dental extraction for severe gingivitis. Vitrectomy was performed 36 days after the onset and vision improved from 0.02 to 0.7. The second patient was referred for acute visual decrease in his left eye. Severe iritis and vitreous opacities were observed, and systemic examination showed acute pyelitis and prostatic abscesses. Blood cultures detected Staphylococcus sp., and systemic antibiotics were given. Vitrectomy was performed 12 days after the onset, and vision improved from 0.06 to 1.2.
Conclusions: We conclude that the rapid treatment with systemic antibiotics for the organisms at the primary site, and the vitrectomy, even though delayed, can lead to a good recovery of vision.
Introduction

Endogenous endophthalmitis is a chorioretinal infection caused by organisms which pass into the eye through the blood stream from a distant organ [1, 2]. This route of infection accounts for 30% of the cases of infectious endophthalmitis, and there has been an increase in the incidence because of the increased number of older patients with sepsis [3]. Systemic and topical antibiotics and vitrectomy are effective, but in general, the visual outcome is poor, and the infection even leads to blindness in some cases [4–9]. The poor outcome is thought to be due to a delay in the diagnosis, virulence of the microorganisms, delay in eye surgery because of a poor systemic condition, and poor wound healing after surgery [4, 5, 10].

We treated two patients with endogenous endophthalmitis caused by Gram-positive cocci who recovered good vision in spite of delayed surgery due to poor systemic conditions.

Case Reports

Case 1

A 60-year-old man noticed that his right eye was inflamed and that he had blurred vision on August 18, 2008. He visited our clinic with complaints of ocular pain and decreased vision OD on September 1, 2008. He had lost 24 kg of body weight during the previous 2 months. On examination, his best-corrected visual acuity (BCVA) was 0.02 OD and 0.6 OS. Intraocular pressure was 20 mm Hg OD and 10 mm Hg OS. Slit-lamp examination revealed severe iritis with fibrin precipitates OD and no particular findings OS. Ophthalmoscopy showed dense vitreous opacity preventing the fundus view OD, and a white mass on the fovea OS. Optical coherence tomography (OCT) showed that the white mass OS was contiguous with the outer retinal layer (fig. 1). Ultrasound echography (US) showed no retinal detachment and the single-flash electroretinogram (ERG) was almost flat OD (fig. 1). Blood tests showed a white blood cell (WBC) count of 12,000/μl composed of 90% neutrophils. C-reactive protein (CRP) was 4.5 mg/dl. Systemic examination showed approximately 3 mm of brain abscess in the left occipital lobe and infectious endocarditis.

Two g/day of imipenem was given intravenously. A thorough discussion with the internist led to the conclusion that the endocarditis and other inflammation should be treated first. The patient underwent mitral valve replacement surgery, and 3 days later, the foveal white mass disappeared and BCVA improved to 1.0 OS. Blood cultures grew Streptococcus anginosus, which was thought to be the cause of the endophthalmitis. The patient was then found to have severe gingivitis and total dental extraction was performed on September 11, 2008. Pars plana vitrectomy (PPL) combined with phacoemulsification (PEA) and intraocular lens (IOL) implantation was performed on September 23. The subretinal abscess and the retina above the inferonasal region were excised, and photocoagulation was performed.

No bacteria were found in the vitreous sample. Three weeks after the vitrectomy, the BCVA OD improved to 0.7, and the patient has kept this vision for 10 months.

Case 2

A 53-year-old diabetic patient was referred on January 19, 2008 because of an acute decrease in the vision OS. His BCVA was 1.2 OD and 0.06 OS, and the intraocular pressure was 18 mm Hg OU. Slit-lamp examination revealed no particular abnormalities OD and ciliary injection and hypopyon OS. Ophthalmoscopy showed diabetic retinopathy OD, and a dense vitreous opacity and a white mass in the nasal retinal region OS. US showed no retinal detachment, and single-flash ERG showed highly reduced a-wave OS (fig. 2). Blood tests showed a WBC count of 12,800/μl composed of 90% neutrophils, 9.5 mg/dl of CRP, and 11.8% of HbA1c. Systemic survey showed acute pyelitis and prostatic abscess. On
January 19, 2 g/day of intravenous imipenem was started and an intravitreal injection of ceftazidime and vancomycin was given. On the next day, the density of the vitreous opacity was reduced OS, and cystostomy was performed. Blood culture revealed coagulase negative *Staphylococcus* sp., which was thought to be the cause of the endophthalmitis. Because bacteremia was found to be absent on January 27, PPL combined with PEA was performed on January 28. A subretinal abscess and the retina above the nasal region were excised and photocoagulation was performed. No bacteria were found in the vitreous samples. Four weeks after the vitrectomy, the BCVA improved to 1.2 OS. The nasal lesion where the subretinal abscess had been resected gradually developed a scar (fig. 2), and the patient underwent secondary IOL implantation OS 5 months later. Clinical findings of the two cases are summarized in **table 1**.

**Discussion**

Ness et al. [8] reported that the visual prognosis depended mainly on the underlying microorganisms, and it was particularly poor in cases of infection with Gram-positive bacteria or *Aspergillus* sp. There is a trend toward early vitrectomy because of the advancement of vitreous surgery [7, 8]. Yoon et al. [7] reported that a retinal reattachment was found in all cases, and counting finger or better VA was attained in half of the cases after early vitrectomy for endogenous *Klebsiella pneumoniae* endophthalmitis in 10 eyes. Although a simple comparison cannot be made, our cases attained very good visual outcome despite delayed surgical treatment. One of the reasons may be that the bacteria were less virulent, and another important factor may be that the primary site of the infection was identified and properly treated before bacteremia developed. The primary infection might have been fatal, and eye surgery was a secondary priority. Thus, vitrectomy had to be delayed, but the end result was still very good. This suggests that early vitrectomy is not absolutely necessary in selected cases.

The culture of the vitreous samples did not grow any bacteria probably due to effect of antibiotics. An earlier vitreous biopsy should have been considered because a culture of the vitreous sample is useful for identifying the responsible bacteria. The positive rate is reported to be 87% for vitreous, 32% for aqueous humor, and 33% for blood [8].

Endogenous endophthalmitis is a complex disease and can be caused by a large number of bacterial species. Thus, a specific treatment method for this disease is not available. However, a rapid identification of the causative organism and of the primary infected site must be done. These identifications may be as important as early vitrectomy, and appropriate systemic antibiotic administration may improve the outcome of vitrectomy as in our cases.

Mo = months; OCT = optical coherence tomography; ERG = electroretinogram; ORL = outer retinal layer.
Fig. 1. Ophthalmological findings of case 1 at onset. a US showed no retinal detachment but an aggregated intravitreal mass in the right eye. b Ophthalmoscopy showed a white mass on the fovea in the left eye. c Optical coherence tomography showed that the white mass shown in b was continuous with the outer retinal layer. d Single-flash ERG showed almost no response in the right eye and normal responses in the left eye.
Fig. 2. Ophthalmological findings of case 2. 

- **a** US showed no retinal detachment but dense vitreal opacity in the left eye.
- **b** Single-flash ERG showed severely attenuated a-wave in the left eye.
- **c** Fundus photograph of the nasal region in the left eye taken 4 weeks after vitrectomy shows a scar where the subretinal abscess was resected.
- **d** Fundus photograph taken 4 weeks after vitrectomy shows no abnormal findings in the left eye.
