ABSTRACT

Context. The high-redshift (\(z = 3.1\)) blazar PKS 0537-286, belonging to the flat spectrum radio quasar blazar subclass, is one of the most luminous active galactic nuclei(AGN) in the Universe. Blazars are very suitable candidates for multiwavelength observations. Indeed, the relativistic beaming effect at work within the jet enhances their luminosity. This in turn allows the properties of the extragalactic jets, the powering central engine, and the surrounding environment to derived.

Aims. Our aim is to present the results of a multifrequency campaign from the near-IR to hard X-ray energies on PKS 0537-286 and give insight into the physical environment where the radiation processes take place.

Methods. We observed the source at different epochs from 2006 to 2008 with INTEGRAL and Swift, and nearly simultaneously with ground-based optical telescopes. We also analyzed two archival spectra taken with XMM-Newton in 1999 and 2005. A comparative analysis of the results is performed.

Results. The X-ray continuum of the blazar, as sampled by XMM, is described by a power law of index \(\Gamma = 1.2\), modified by variable absorption at the soft X-rays, as found in other high-redshift QSOs. Modest X-ray continuum variability is found in the Swift observations. The combined Swift/BAT and Swift/XRT spectrum is very hard (\(\Gamma = 1.3\)). This, together with the non simultaneous EGRET detection and the more recent non detection by Fermi-LAT, constrains the peak of the high-energy component robustly. The optical/UV data, heavily affected by intervening Ly \(\alpha\) absorption, indicate the presence of a bright thermal accretion disk that decreased in luminosity between 2006 and 2008. We infer from this a reduction of the BLR radius. When taking this into account, the 2006 and 2008 SEDs are compatible with a model based on synchrotron radiation and external inverse Compton scattering where the accretion-disk luminosity decreases between the 2 epochs by a factor 2, while the bulk Lorentz factor remains unchanged and the magnetic field changed only marginally.

Key words. quasars: individual (PKS 0537-286) – galaxies: active – X-rays: galaxies – galaxies: high-redshift – radiation mechanisms: nonthermal

1. Introduction

Simultaneous multiwavelength studies of blazars offer a tool for determining the properties of extragalactic jets, their powering central engine, and the surrounding environment. The alignment of the jet with respect to the observer’s line of sight (Antonucci 1993; Urry & Padovani 1995) makes blazars very luminous from radio frequencies to gamma-ray energies (Ulrich et al. 1997). Indeed, the beaming in these relativistic outflows (Rees 1966) enhances the luminosity. While the jet propagates, part of its power is dissipated via cooling and acceleration processes of protons and leptons. The emitting particles, together with the relativistic beaming, give rise to the typical two broad hump structure of the spectral energy distribution (SED). The low-energy emission is understood and is believed to be produced through synchrotron radiation of relativistic electrons. In contrast, the nature of the high-energy hump is still being debated. A possible explanation is that the same electron population that is responsible for the low-energy hump generates the high-energy hump through the inverse-Compton mechanism (Sikora et al. 1994; Dermer & Schlickeiser 1993; Ghisellini & Madau 1996). Another model predicts that the seed photons for the inverse-Compton are external to the jet (Sikora et al. 1993; Dermer et al. 1992). Alternative explanations are proton-initiated cascades (Mannheim 1993) or proton-synchrotron emission from ultrarelativistic protons (Mücke et al. 2003; Aharonian 2000).

High-redshift blazars are important tracers of the evolution of super massive black holes (SMBH) in the early Universe. Böttcher & Dermer (2002) link the two blazar subclasses, namely flat spectrum radio quasars (FSRQ) and BL the Lacertae (BL Lac) objects, which are the beamed counterparts of low- and high-luminosity radio galaxies, respectively (Wall & Jackson 1997; Willott et al. 2001), through the gradual depletion of the circum-nuclear environment of SMBHs. In a process that is not understood well, the interaction of the accretion disk and the SMBH drives the formation of jets. The blazar spectra therefore carry the information about the accre-
tion and the circumnuclear environment, hence on the evolution of the environment of SMBHs over cosmic time. Indeed, a general characteristic of radio-loud quasars at high redshift is an apparent absorption in excess of the Galactic value (Fiore et al. 1998; Reeves & Turner 2000). The nature of this X-ray spectral feature is still controversial. Obtaining precise spectra of blazars allows us to understand the physics at work in jets and derive information on the environment where the jet propagates. This in turn can confirm or deny evolutionary scenarios of blazars.

PKS 0537-286, at $z = 3.104$ (Wright et al. 1978), is one of the most luminous known high-redshift quasars. First detected at radio frequencies (Bolton et al. 1975), it was observed at X-rays by the Einstein observatory (Zamorani et al. 1981) and later studied with ASCA (Cappi et al. 1997; Siebert et al. 1996), ROSAT (Fiore et al. 1998), XMM (Reeves et al. 2001) and Swift (Sambruna et al. 2007). These observations showed an extremely luminous quasar ($L_x = 10^{47}$ erg s$^{-1}$ in the 0.1 - 2 keV range) with a particularly hard spectrum ($\Gamma = 1$ measured by Swift/BAT) and a weak iron K emission line and reflection features. Moreover, Sowards-Emmerd et al. (2004) identified PKS 0537-286 as probable counterpart of the EGRET source 3EG J0531-2940 (Hartman et al. 1999).

In this paper we report on a multiwavelength campaign on PKS 0537-286 ranging from the near-IR/optical to hard X-ray energies. In S. 2 we describe the observations of the 2006 and 2008 multiwavelength campaigns; and in S. 3 the archival 2005 XMM observations; in S. 4 we report the results of our multiwavelength observations and of the XMM archival data; in S. 4 we discuss the results.

2. Observations

2.1. The 2006 to 2008 multiwavelength campaign

The source was monitored by INTEGRAL. Since the Swift/BAT light curve over 9 months of exposure (Ajello et al. 2008a) showed a constant flux level, the INTEGRAL pointings were performed in non-contiguous time intervals. ISGRI detected the source at 5.6 $\sigma$. In order to cover simultaneously the X-ray and UV ranges we requested Swift ToOs. These observations were scheduled on October 27th, 30th, 31st 2006 and further Swift/XRT observations were executed on February 10th, 12th 2008. Simultaneously to the Swift pointings REM, GROND, and Palomar 60-inch telescope performed photometry. RXTE PCA observed PKS 0537-286 on November 1st 2006 in the 3 - 20 keV band. Details of the multiwavelength campaigns can be found in Tables 1 to 6.

2.1.1. UV to optical observations

UVOT. – PKS 0537-286 was targeted in the U-band with the UV-Optical Telescope UVOT (Roming et al. 2005) onboard the Swift satellite. Observations were performed in three epochs in 2006 October and two epochs in 2008 February (Table 1). Here, we use the standard pipeline reduced image products, co-added and exposure corrected within the XIMAGE environment.

Palomar. – $B$ and $V$-band observations with the robotic Palomar 60-inch telescope (Cenko et al. 2006) were carried out in eight nights between 2006 Oct 26.4 UT and 2006 Nov 2.9 UT (Table 2). Data were reduced with standard IRAF routines

2.2. X-ray observations

INTEGRAL. – The INTEGRAL satellite observed the source for 1 Ms with its imager IBIS/ISGRI (Lebrun et al. 2003) which operates in the range of 17 - 1000 keV. The long exposure of 1 Ms was carried out in non-consecutive pointings. These observations were performed with a rectangular $5 \times 5$ dithering pattern and reported in Table 5. We used the standard Off-line Science Analysis (OSA – Courvoisier et al. 2003) software version 7.0 for the ISGRI analysis. Using the detected count rate we performed data cleaning. Most recent matrices available for standard software (isgri.arf, rsp0225.fits) were used for spectral analysis. We used 296 science windows for a total amount of 981

ksec of exposure time on the source. The source is detected with ISGRI in the 17 - 55 keV energy range with a significance of 5.6 sigma. Data screening was performed according to the median count rate with respect to each science window and its distribution. Because of the low detection level a spectrum could not be extracted. The adopted dithering pattern resulted in a limited coverage of the source by JEM-X (Joint European Monitor for X-rays). Thanks to its large field of view, BAT surveys up to 80% of the sky every day. We selected all observations of PKS 0537-286 comprised in the time span January 2006 - March 2008. The data were processed using HEAsoft 6.3 and following the recipes presented in Ajello et al. (2008a). The spectrum and the light curve of PKS 0537-286 were extracted using the method presented in Ajello et al. (2008b).

3. XMM-Newton archive data

We searched for observations of PKS 0537-286 in the XMM-Newton archive and found a 80 ks observation of the source (obs-id 02063502-01) still unpublished. The source has been observed with the EPIC imagers. Data were linearized by applying the most recent calibrations with the software XMM-SAS version 9.0. We have extracted the light-curve of the background in the 10-15 keV energy range and excluded with a 3σ clipping technique a time interval of flaring particle background. Since the spectrum of many soft-proton flares may be extremely soft, we repeated the light-curve screening in the 0.3-10 keV energy band and excluded time interval with high background flux. As a result, most of the observing time has been lost because of particle flares and the final sum of the good time interval yields an effective exposure of ~8 ks.

By using the same software package we extracted the EPIC-PN spectrum of the source in a circle with a radius of 40 arcsec. The background has been evaluated on a similar area of the same PN-CCD, but far from source readout features. As a result the final sum of the good time interval yields an effective exposure of ~8 ks.
We further analyzed the XMM-Newton data of PKS 0537-286 observed during orbit 51 (but with latest response) in 1999 and reproduce the fit results as reported in Reeves et al. (2001).

4. Results

4.1. Variability analysis

Each single optical light curve obtained with REM, GROND and P60 does not show significant variations. Whenever, if at a given date, more than one REM, GROND or Palomar measurements are available, then the average flux is taken. Among the observations performed with the different optical instruments (this means among long time scales) the source showed variability as can be seen in Tables 2, 3, 4. Within each individual Swift/XRT pointing just very marginal flux variation in the XRT spectrum was found (Table 7). Considering the large uncertainties among the five pointings, the flux amplitude is ~8%. The BAT light curve is consistent with being constant over the 2 years of the survey.

4.2. Swift and RXTE spectra

The fit results of the single spectra of each single instrument are shown in Table 7. The spectra were fitted using XSPEC 12 and the latest available response matrices for calibration. The spectra are exceptionally hard. Swift/BAT detected, in the 15 - 150 keV range, PKS 0537-286 with a flux of ~ 3 × 10^{-11} erg cm^{-2} s^{-1} during the two years of the survey. The low Galactic N_H-value (2.0 × 10^{20} cm^{-2}) as given by Kalberla et al. (2005) does not affect the BAT energy range, and we do not see evidence of further absorption or deviations from a simple power law.

Since the lower limit of the energy range is around 2 keV also the RXTE spectrum is not affected by absorption features. Therefore also this spectrum is well represented by a simple power law.

The best fit results (χ^2_red < 0.9) for each single Swift/XRT spectrum is given by an absorbed power-law model, with absorption parameter free to vary. Given the large fit uncertainties, reflecting the poor quality of these spectra, it is impossible to fully constrain the obtained parameters.

Since we would like to assess the spectral characteristics with the best possible S/N, we have joined the average BAT, XRT and RXTE spectra and fitted the combined spectrum. The fit results are listed in Table 7.

In the case of the co-added XRT, RXTE and BAT spectra we model the data with a power law with Galactic absorption controlled by the hydrogen column density. The large errors of the fitted parameters do not allow to constrain the absorption parameter.

4.3. XMM spectra

First we have checked the consistency of the single X-ray spectra among the 3 EPIC detectors within the single observations by fitting power-law model as in Reeves et al. (2001). Our reanalysis of the observation in 1999 (orbit 51) confirms the results reported by Reeves et al. (2001), where a simple power-law model fits the spectrum to a spectral index Γ = 1.22 ± 0.08 with χ^2(dof) = 983(808). By fitting these data to an absorbed power law, the absorption parameter is consistent with the Galactic hydrogen column density. Therefore no absorption in addition to the Galactic N_H is required, confirming once more the results in Reeves et al. (2001).

^afluxes are computed in the following energy ranges for the different instruments: XRT 0.6 - 6.0 keV; RXTE 3 - 20 keV; BAT 15 - 150 keV.

![Fig. 1. Data-to-model ratio for PKS 0537-286 as observed by XMM in 2005. The fitted model is a power law (including Galactic absorption) in the 0.3 - 8.0 keV energy range. The model is inadequate. The data are rebinned for demonstration to have at least a significant detection of 15 σ. The pn data are represented by squares, while circles and stars represent MOS-1 and MOS-2, respectively.](image)

Contrary to the observation in 1999, the spectra derived from the observation in 2005 show an apparent absorption in excess to the Galactic value at ~7 σ. Figure 1 shows the data-to-model ratio of the best-fit power law modified by the Galactic absorption (with χ^2(dof) = 1110(1013)). Besides falling to ~ 0.8 for the softest energies, the residuals exhibit emission in excess between 1 - 2 keV. This is similar to what is found by Yuan et al. (2005), Worsley et al. (2004a) and Tavecchio et al. (2007) for other high-redshift blazars. Therefore the spectrum modeled by an absorbed power law with χ^2(dof) = 1015(1012). Figure 2 shows the confidence level contour plot of the absorption in excess to the Galactic value N_H and the spectral index. In order to reproduce this clear spectral feature, we add another component to the base line model (wabs*powerlaw) and fit the photoelectric absorption component fixed to the Galactic value convolved with the intrinsic absorption component and a power law (wabs*(zwabs*powerlaw)). The resulting intrinsic absorption

value is N_H ~ 4.8×10²¹ cm⁻². Table 8 shows the fit results of the co-added PN, MOS-1 and MOS-2 spectrum.

A fit of the spectrum with a power law and black body, modified by Galactic absorption as suggested in Celotti et al. (2007), gives an acceptable fit (χ²_red = 1.04). But there is only marginal improvement of the χ²_red (1.09) obtained fitting the power law with absorption fixed to the Galactic value. We further show that the same spectrum is modeled with χ²_red = 1.04 by a power law and free absorption parameter. Figure 3 shows the unfolded spectrum fitted to the latter model in E²f(E) space.

A systematic spectral flattening of high-redshift blazars at low X-ray energies was found previously (Fiore et al. 1998; Reeves & Turner 2000). Similarly Worsley et al. (2004) detected a convex spectrum for the blazar PMN J0525-3343 at z = 4.4, and argued that it is most likely produced by a warm (ionized) absorber intrinsic to the source. We probed this hypothesis for PKS 0537-286 by fitting a power law and the contribution of ionized media intervening between source and the observer that modify the source flux in an energy-dependent way. The warm absorber hypothesis results in an absorbing ionization state ξ = 150±50 erg cm⁻² s⁻¹.

The XRT flux in the 0.6 - 6.0 keV band is systematically lower than the flux in the same energy band seen in XMM. Moreover, the spectral index of the XMM spectrum is slightly harder than the one of the XRT spectra. This suggests significant

5. The spectral energy distribution

We constructed two multiwavelength spectra using the data of the first and fourth epochs (corresponding to the XRT pointings on October 27th 2006 and on February 10th 2008) of our campaign, and adding to these non-simultaneous multiwavelength data, including an EGRET detection in three energy bins in the GeV range. The optical and UV data were corrected for Galactic absorption using E(B-V) = 0.025 mag (Schlegel et al. 1998), and converted into fluxes. The optical flux at wavelengths shorter than ~5000 Å is significantly suppressed by the Ly α intervening absorption (Weymann et al. 1981). Therefore is the sharp increase from UV towards optical band not surprising, as the Ly α forest is shifted along lower frequencies due to the high-redshift. PKS 0537-286 belongs to the FSRQ subclass of blazars. The typical two hump structure is evident in the two SEDs. The IC peak can be constrained by the BAT data points and EGRET data to be located at a few GeV. The synchrotron peak is somewhat difficult to determine.

We model the data according to Ghisellini & Tavecchio (2009), assuming a one-zone, homogeneous synchrotron and inverse-Compton model. The ejecta move within the jet seen under an angle and bulk Lorentz factor Γ. The homogeneous mag-

Explaination of columns: (1) = dissipation distance in units of 10^{18} cm and (in parenthesis) in units of 10^{19} R_s; the (spherical) emitting size is ten times smaller; (2) = black hole mass in 10^8 solar masses; (3) = size of the BLR in units of 10^{15} cm; (4) = power injected in the blob calculated in the comoving frame, in units of 10^{45} erg s^{-1}; (5) = accretion-disk luminosity in units of 10^{45} erg s^{-1} and (in parenthesis) in units of L_{Edd}; (6) = magnetic field in Gauss; (7) = bulk Lorentz factor at $R_{\text{diss}}$; (8) = viewing angle in degrees; (9) and (10) = break and maximum random Lorentz factors of the injected electrons; (11) and (12) = slopes of the injected electron distribution (Q(\gamma)) below and above $\gamma_b$.

Table 10. List of parameters used to construct the theoretical SED.

| log $P_i$ | log $P_B$ | log $P_e$ | log $P_p$ |
|-----------|-----------|-----------|-----------|
| (1)       | (2)       | (3)       | (4)       |
| 46.5      | 45.3      | 46.6      | 48.0      |
| 46.2      | 45.0      | 46.4      | 48.0      |

Explaination of columns: (1), (2), (3) and (4): jet power in the form of radiation, magnetic field, bulk motion of electrons and protons (assuming one proton per emitting electron). These powers are derived quantities, not input parameters. For all cases the X-ray corona luminosity $L_X = 0.3 L_d$. Its spectral shape is assumed to be $\propto \nu^{-1} \exp(-h\nu/150 \text{ keV})$.

6. Discussion

It is unlikely that the apparent excess column density for PKS 0537-286 is of Galactic origin. It would require absorption by cold material with a column of $N_H \sim 2.5 \times 10^{20}$ cm^{-2} in addition to the Galactic level toward the direction of the source. The Galactic hydrogen column density derived within different energy bands (IR, radio) by Schlegel et al. (1998), Elvis et al. (1989) and Kalberla et al. (2005) enforces the accuracy of the measured Galactic $N_H$. Also the intergalactic origin is highly improbable because the line of sight would have to intercept several systems with very high column density. The chance probability to intercept several very high column density Ly $\alpha$ absorption systems is very low (p < 2%) (O'Flaherty & Jakobsen 1997). Furthermore, we exclude that the damped Ly $\alpha$ absorption systems (DLA) contribute significantly to the spectral absorption feature. In fact, the DLA at z = 2.974, associated with an intervening galaxy, has HI column density of log$N_{HI} = 20.3 \pm 0.1$ (Akerman et al. 2005) and metallicity below half solar. This would give an absorption at soft X-ray energies caused by a column density of $N_H < 10^{20}$ cm^{-2}. The intrinsic absorber hypothesis is much debated. For this absorber we derived a high column density value of $N_H \sim 4.8 \times 10^{21}$ cm^{-2}. Under the warm absorber hypothesis we cannot constrain the ionization state of...
Fig. 4. Observed spectral energy distribution of PKS 0537-286 on 27 October 2006 (black filled circles) and 10 February 2008 (red filled circles). The filled green triangles represent the Swift/BAT spectrum extracted from the 2 years survey. The data are corrected for Galactic extinction. Gray points are archival data. The dotted line shows the single components to the SED from the IR torus, the disk and the X-ray corona. The purple solid line represents the 5σ sensitivity of Fermi after one year mission time. The jet model Ghisellini & Tavecchio (2009) for the energy distribution for 27 October 2006 (orange solid curve) and 10 February 2008 (blue solid curve) are overplotted.

The possible absorbing material better than $\xi = 150_{-0.0}^{+450} \text{ erg cm}^{-2} \text{s}^{-1}$. Furthermore, the best evidence for warm absorbers, like the O absorption edge and the Fe M-shell, are down shifted outside our observed range (0.3 - 10 keV) being in the rest frame’s energy band within 0.5 - 0.9 keV. The possibility for the warm absorber to give rise to absorption variability (Reeves & Turner 2000) is not confirmed in our case.

The excess absorption, also referred to as spectral flattening, has been reported several times for this source (Cappi et al. 1997; Fiore et al. 1998; Sambruna et al. 2007). Spectral flattening is in agreement with a general behavior seen in a number of high-redshift radio-loud quasars studies (Fiore et al. 1998; Reeves & Turner 2000), where the required column density is up to $10^{22} \text{ cm}^{-2}$, whereas low-redshift blazars show unabsorbed spectra. If the flattening is not a mere selection effect due to the high-redshift, then this could indicate an evolutionary scenario. In fact, the positive evolution of FSRQs (Dunlop & Peacock 1990) foresees a bulk of FSRQs at high-redshift. PKS 0537-286 shows time variability of the apparent excess column density. Figure 5 shows the time variability of the column density over 7 years as measured by several instruments. Similarly Schartel et al. (1997) find variable absorption of X-rays for a
Fig. 5. Time variability of $N_H$ measured by several instruments. From left to right the instruments are: ROSAT (Cappi et al. 1997), two ASCA upper limits (Siebert et al. 1996), XMM (this work), Chandra 3 or upper limit (this work), XMM (this work). The dashed horizontal line delimits the Galactic hydrogen column density (Kalberla et al. 2005).

high-redshift blazar on time scales of $< 1.5$ years. At present the origin of this absorption is unknown.

Inspection of the SEDs allows us to constrain the inverse Compton peak rather well, thanks to the exceptionally hard X-ray spectrum and the EGRET data. Moreover, our source is not included in the Fermi bright source list (Abdo et al. 2009), indicating that the upper limit is consistent. The model does not account very well for the shorter wavelength optical data, because of the Ly $\alpha$ drop. An optical flux excess in the 2nd epoch is partially due to strong emission lines contaminating the GROND filters. The chosen parameters for the 1st observation epoch deviate from those obtained for the same source by Sambruna et al. (2007) and modeled using Ghisellini et al. (2002). This is due to our accurately sampled data, that allow us to better constrain the theoretical SED.

7. Conclusions

We have conducted a multifrequency campaign on PKS 0537-286 on six different epochs. The source was monitored nearly simultaneously from optical to gamma-rays. In the optical - near-IR band the most evident flux variations were observed between the observations on October 27th 2006 and on February 10th 2008. The compiled SED for the latter two observation epochs allowed to derive the physical parameters of the source. Also a new and detailed X-ray spectroscopic study of the XMM-Newton observation in 2005 of the source has been presented. The spectral flattening for this source at soft X-ray energies, reported previously by Cappi et al. (1997), Fiore et al. (1998) and Sambruna et al. (2007), is confirmed by the high signal-to-noise XMM spectra. This flux decrease at soft X-ray energies cannot be attributed to excess absorption in the Milky Way or to intervening material in the intergalactic medium along the line of sight to the source. Data suggest that the absorber can be intrinsic to the source. By using our data and searching in literature we have constructed a time curve of the $N_H$ for the source. We confirm the variability of the apparent excess absorption on time scale of years. A periodicity for this spectral feature cannot be inferred. Our result highlights once more the evidence for the existence of a population of superluminous blazars at high-redshift that show a soft X-ray cut-off. If the bulk at high-redshift of these type of sources is not only due to selection effect, then their existence is important in the context of cosmological evolution of SMBHs (Böttcher & Dermer 2002).
