Abstract. We consider non-interacting particles (or lions) performing one-dimensional random walks or Lévy flights (with Lévy index $1 < \mu \leq 2$) in the presence of a constant drift $c$. Initially these random walkers are uniformly distributed over the positive real line $z \geq 0$ with a density $\rho_0$. At the origin $z = 0$ there is an immobile absorbing trap (or a lamb), such that when a particle crosses the origin, it gets absorbed there. Our main focus is on (i) the flux of particles $\Phi_c(n)$ out of the system (the ‘Smoluchowski problem’) and (ii) the survival probability $S_c(n)$ of the trap or lamb (the ‘lamb-lion problem’) until step $n$. We show that both observables can be expressed in terms of the average maximum $\mathbb{E}[M_c(n)]$ of a single random walk or Lévy flight after $n$ steps. This allows us to obtain the precise asymptotic behavior of both $\Phi_c(n)$ and $S_c(n)$ analytically for large $n$ in the two problems, for any value of $1 < \mu \leq 2$ and $c \in \mathbb{R}$. In particular, for $c > 0$ and $1 < \mu < 2$, we show that $S_{c>0}(n \rightarrow \infty)$ vanishes as $S_{c>0}(n \rightarrow \infty) \approx \exp(-\lambda n^{2-\mu})$, where $\lambda$ is a $\mu$-dependent positive constant, in contrast with the case of standard random walks (i.e. with $\mu = 2$) for which $S_{c>0}(n \rightarrow \infty) \rightarrow K_{RW} > 0$. Our analytical results are confirmed by numerical simulations.

Keywords: Brownian motion, extreme value
1. Introduction

Brownian motion and random walks have been fundamental cornerstones of statistical physics for more than a century. While Brownian motion is the building block for processes with continuous trajectories, random walks underlie processes with countable increments built from jumps occurring at discrete time steps. Both have a large number of applications in a wide range of fields [1–5].

Consider first the case of a Brownian motion in the presence of a constant drift $c$ in one dimension. Its position $x(t)$ on the line evolves, with time $t$, according to

$$\frac{dx(t)}{dt} = c + \sqrt{2D} \eta(t),$$

starting from $x(0) = 0$, where the drift $c$ is a fixed number, $D$ is the diffusion constant, and $\eta(t)$ is a Gaussian white noise with zero mean and delta correlator, $\langle \eta(t)\eta(t') \rangle = \delta(t - t')$. For a discrete-time random walk (RW) with a constant drift $c$, the counterpart of equation (1) reads

$$x_i = x_{i-1} + c + \eta_i,$$

giving the evolution of the position $x_i$ of the walker after $i$ steps, for $i \geq 1$, starting at $x_0 = 0$. The jump increments $\eta_i$‘s are independent and identically distributed (i.i.d.) random variables, each drawn from a symmetric and piecewise continuous probability
distribution function (PDF) $f(\eta)$. Adding a drift to the standard Brownian motion and random walks allows to study the effect of linear trends in several fluctuating observables of interest such as statistics of records [6, 7] with specific applications to finance [8–10].

In this paper, we study the effect of a constant drift in two random walk problems, namely the celebrated Smoluchowski flux problem and the so called ‘lamb-lion’ problem that is defined precisely later. These two problems have been studied before for Brownian motions without drift and several exact results are known in this case. Here we establish new results for Brownian motions as well as discrete-time random walks/Lévy flights both in the presence of a constant drift $c$. The original line followed in this work consists in re-expressing the problems in terms of the a priori unrelated expected maximum, $\mathbb{E}[M_c(t)]$, where $M_c(t) \geq 0$ denotes the maximum position of a walker up to time $t$, with $t \in \mathbb{R}^+$ if the walker position is given by equation (1) (continuous-time Brownian motion), or $t \in \mathbb{N}$ if it is given by equation (2) (discrete-time RW). Then, we make use of our recent exhaustive study of the asymptotic large time behavior of $\mathbb{E}[M_c(t)]$ [11] to determine how the Smoluchowski and ‘lamb-lion’ problems are affected by a constant drift $c$. More specifically, the main new results we have obtained along this line are (i) establishing the relations (3) and (4) below, and (ii) deriving explicit expressions of the right-hand side of (3) and (4) by using recent results on $\mathbb{E}[M_c(t)]$ derived in [11].

The two problems we solve in this paper follow from the situation where one considers a semi-infinite line $z \in [0, \infty)$ with a single immobile trap, or absorber, at the origin $z = 0$. Initially, the full semi-infinite line to the right of the trap is filled uniformly by non-interacting particles with uniform density $\rho_0$. Each particle performs an independent random walk as in equation (1) or (2) with a drift $c$. When a particle crosses the trap at the origin, it gets absorbed in the sense that it is immediately (and permanently) removed from the system (see figure 1). There are then two natural and interesting questions related to this physical situation.

The first one is the one-dimensional (1D) version of the celebrated Smoluchowski problem [12] where one is interested in the net flux $\Phi_c(t)$ of particles out of the system up to time $t$. Interestingly, on can show that this flux is directly related to the expected maximum via the relation

$$\Phi_c(t) = \rho_0 \mathbb{E}[M_c(t)],$$

(3)

the derivation of which is given below in section 3.1 (for continuous-time Brownian motion) and in section 3.2 (for discrete-time RW). The somewhat unexpected appearance of $M_c(t)$ in this problem can be explained heuristically as follows. Consider a particle located at some given $z > 0$ at time $t$. The trajectory of this particle, looked at backward in time, is a realization of a random walk with drift $-c$ starting from $z$ and never crossing the origin up to time $t$ (otherwise it would have been removed from the system). Taking $z$ as a new origin and reversing space direction turns it into a realization of a random walk with drift $c$ starting from 0 and always staying below $z$ up to time $t$, i.e. a realization with $M_c(t) \leq z$ (this is where $M_c(t)$ comes into play). Now, consider a system where non-interacting particles are placed initially on the positive axis with uniform density $\rho_0$. It follows from the same argument applied to the trajectories of all the particles located at $z$ (to within $dz$) at time $t$, and from $\rho_0$ being uniform,
that the density of these particles (at time $t$) must be proportional to $\text{Prob}[M_c(t) \leq z]$ (see equation (40) or (52)). Relation (3) then follows from a space integration (see equations (22) and (38), or (28) and (50)).

The second question, in the same physical setting, is the survival probability of the trap, $S_c(t)$, up to time $t$. More precisely, $S_c(t)$ is the probability that none of the particles, initially uniformly distributed with density $\rho_0$, has hit the origin up to time $t$. For the case $c = 0$, the survival probability $S_0(t)$ has been computed exactly and is generally known as the target-annihilation problem [13–16] (for a recent review see [17]). Sometimes, this problem is also known as the lamb-lion problem: an immobile lamb is located at the origin $z = 0$, while $N$ lions with initial positions uniformly distributed over the interval $z \in (0, L)$ undergo independent Brownian motions. A variant of this problem where the lamb itself performs Brownian motion has generated a considerable interest and still remains unsolved to a large extent [18–25]. Here, we consider this target annihilation problem with an immobile lamb at the origin while the lions perform (i) independent Brownian motions with a constant drift $c$ and (ii) independent random walks/Lévy flights with a constant drift $c$. Our main objective is to compute the survival probability $S_c(t)$ of the lamb in these two cases in the thermodynamic limit: $L, N \to \infty$ keeping $\rho_0 = N/L$ fixed. In this thermodynamic limit, we show below that $S_c(t)$ is related to the expected maximum $\mathbb{E}[M_c(t)]$ of a single random walk/Lévy flight that starts at the origin (see sections 4.1 and 4.2)

$$S_c(t) = \exp \left[ -\Phi_{-c}(t) \right] = \exp \left[ -\rho_0 \mathbb{E}[M_{-c}(t)] \right],$$

(4)
where we have used equation (3) in the last equality. For the case \( c = 0 \), this relation connecting the survival probability to the expected maximum \( S_0(t) = \exp(-\rho_0\mathbb{E}(M_0(t))) \) was established in [16]. Note that our result in equation (4) is valid for both biased Brownian motion and biased random walks/Lévy flights—in the latter case \( t \) refers to the discrete time step \( n \).

The relations in equations (3) and (4) establish a nice link between the expected maximum \( \mathbb{E}[M_c(t)] \), the integrated flux \( \Phi_c(t) \), and the survival probability \( S_c(t) \), providing thus two nontrivial physical applications for the expected maximum of a random walk with a drift. These questions are quite well understood for the Brownian motion (1) which, by virtue of the central limit theorem, describes the large \( n \) limit of random walks (2) with jumps having a well defined second moment, \( \int_{-\infty}^{\infty} \eta^2 f(\eta) \, d\eta < +\infty \).

In the absence of a drift, i.e. for \( c = 0 \), it is well known that the expected maximum behaves as [5]

\[
\mathbb{E}[M_0(t)] = \frac{2}{\sqrt{\pi}} \sqrt{Dt}.
\] (5)

For \( c \neq 0 \), the expected maximum behaves quite differently. Indeed, for large \( t \), one has (see [11] for a simple derivation of both (5) and (6))

\[
\mathbb{E}[M_c(t)] \sim \theta(c) ct + \frac{D}{|c|} \quad (t \to \infty),
\] (6)

where \( \theta(c) \) is the Heaviside step function, \( \theta(c) = 1 \) if \( c > 0 \) and \( \theta(c) = 0 \) if \( c < 0 \). From the results in equations (5) and (6), together with the relation in equation (4), it follows that the large time behavior of the survival probability \( S_c(t) \) in the case of Brownian motion is given by

\[
S_c(t) \sim \begin{cases} 
K_{BM} \exp\left(-\rho_0 |c| t\right), & c < 0 \\
\exp\left(-\frac{\rho_0}{\sqrt{\pi}} \sqrt{Dt}\right), & c = 0 \\
K_{BM}, & c > 0
\end{cases} \quad (t \to \infty),
\] (7)

where \( K_{BM} = \exp(-D\rho_0/|c|) \) is a constant, which shows in particular that if \( c > 0 \) then the lamb (or trap) will survive with a finite probability as \( t \to \infty \).

In our previous paper [11] we addressed the interesting question of how equations (5) and (6) get affected when the continuous-time Brownian motion (1) is replaced by a discrete-time Markov process like in (2), including Lévy flights. To this end we considered jump PDFs, \( f(\eta) \), the Fourier transform of which \( \hat{f}(k) = \int_{-\infty}^{\infty} e^{ik\eta} f(\eta) \, d\eta \) has the small \( k \) behavior

\[
\hat{f}(k) = 1 - |ak|^{\mu} + O(|k|^\nu),
\] (8)

where \( a > 0 \) is the characteristic length scale of the jumps, \( 1 < \mu \leq 2 \) is the Lévy index, and the subleading exponent \( \nu > \mu \), (note that we need \( \mu > 1 \) for \( \mathbb{E}[M_c(t)] \) to exist). For \( \mu = 2 \), the variance of the jump distribution \( \sigma^2 = \int_{-\infty}^{\infty} \eta^2 f(\eta) \, d\eta \) is finite and \( a = \sigma/\sqrt{2} \).

In this case, the suitably scaled RW converges to a Brownian motion as \( t \to +\infty \). On the other hand, for \( 0 < \mu < 2 \), \( f(\eta) \) is a fat-tailed distribution, \( f(\eta) \propto |\eta|^{-1-\mu} (\eta \to \infty) \), and the RW (2) is a Lévy flight of index \( \mu \). In the following we write \( n \equiv t \in \mathbb{N} \) the
(discrete) time variable pertaining to the discrete-time RW (2). In the absence of a drift, i.e. for \( c = 0 \), it was found in [26] that the discrete-time counterpart of equation (5) reads

\[
\mathbb{E}[M_0(n)] \sim a\mu\Gamma(1-1/\mu)\frac{n^{1/\mu}}{\pi} + a\gamma \quad (n \to +\infty),
\]

with

\[
\gamma = \frac{1}{\pi} \int_0^{+\infty} \ln \left( \frac{1-f(q/a)}{q^\mu} \right) \frac{dq}{q^2}.
\]

It is important to notice that, while the leading term on the right-hand side of equation (9) gives the leading large \( n \) behavior of \( \mathbb{E}[M_0(n)] \) correctly for all \( \nu > \mu \) (see equation (8)), the next subleading correction needs \( \nu > \mu + 1 \) to be a constant. In the complementary domain \( \mu < \nu < \mu + 1 \), one finds that \( \gamma \) in equation (9) must be replaced with a term growing as \( n^{1-(\nu-1)/\mu} \) [27]. For simplicity, in the following we will always assume that in the absence of a drift, \( c = 0 \), the inequality \( \nu > \mu + 1 \) is fulfilled.

For \( \mu = 2 \) one has

\[
\mathbb{E}[M_c(n)] \sim \theta(c) c n + |c| \kappa_c \quad (n \to \infty),
\]

with

\[
\kappa_c = \frac{1}{2\pi} \frac{\partial}{\partial \lambda} \left. \int_{-\infty}^{+\infty} \ln[1-f(q/c)e^{-iq}] \frac{dq}{\lambda + i\lambda} \right|_{\lambda=0},
\]

and for \( 1 < \mu < 2 \), one finds

\[
\mathbb{E}[M_c(n)] \sim \theta(c) c n + |c| \frac{C n^{2-\mu}}{2-\mu} \quad (n \to \infty),
\]

where

\[
C = \frac{\Gamma(\mu-1)}{\pi} \sin \left( \frac{\pi\mu}{2} \right) \left( \frac{a}{|c|} \right)^\mu.
\]

Using then equations (9), (11) and (13) on the right-hand side of the general relation (4) yields the large \( n \) behavior of the survival probability \( S_c(n) \) in the case of a discrete-time lion RW. For a random walk with \( \mu = 2 \), one gets

\[
S_c(n) \sim \begin{cases} 
K_{RW} \exp \left( -\rho_0 |c| n \right), & c < 0 \\
K_{RW}^{(0)} \exp \left( -\frac{2\rho_0}{\sqrt{\nu}} \sqrt{n} \right), & c = 0 \\
K_{RW}, & c > 0 
\end{cases} \quad (n \to \infty),
\]

where \( K_{RW}^{(0)} = \exp(-a\rho_0\gamma) \) and \( K_{RW} = \exp(-|c|\rho_0\kappa_c) \) are constants (note that \( \kappa_{-c} = \kappa_c \)). On the other hand, for a Lévy flight with \( 1 < \mu < 2 \), one finds

https://doi.org/10.1088/1742-5468/ab35e5

J. Stat. Mech. (2019) 083214
where $\mathcal{S}(n)$ and $\mathcal{S}(n)$ are slowly varying compared respectively with the exponential of $n$ and $n^{2-\mu}$, with $\mathcal{S}(n) = \mathcal{S}(n) \exp[-n^{2-\mu}|c|\rho_0 C/(2 - \mu)]$. Note that the numerical value of the constant $K_{\text{RW}}^{(0)}$ in equation (16) is not the same as in equation (15), as $\gamma$ in equation (10) depends on $\mu$. The growth of $\mathbb{E}[M_c(n)]$ in equation (13) for $1 < \mu < 2$ and $c < 0$ is somewhat unexpected since, in this case, the process $y_n = x_n - c n$, with $x_n$ given by equation (2), converges to a symmetric Lévy flight for large $n$ with $y_n = O(n^{1/\mu})$, typically. This is much smaller than the drift term $c n$ and one could thus legitimately expect $\mathbb{E}[M_c(n)]$ to converge to a constant for large $n$, like in the $\mu = 2$ case in equation (11). This is not the case: for $c < 0$, although the walker will typically drift to $-\infty$, she/he will always perform rare big jumps that will contribute to higher and higher values of $\mathbb{E}[M_c(n)]$ significantly as $n$ increases. An interesting consequence of this result on the lamb-lion problem, for lions undergoing independent Lévy flights with a constant drift, is that the survival probability of the lamb (or trap) still decays to zero in the presence of a positive drift, as can be seen in the third equation (16). Albeit a bit counterintuitive, this result is now easy to understand: lions will always perform rare big jumps that will overcompensate for their linear drift away from the lamb.

Note that the large $n$ behavior of $\mathbb{E}[M_c(n)]$ in equation (13), as well as the corresponding expressions of $\Phi_c(n)$ and $S_c(n)$, via equations (3) and (4), are leading behaviors only. As we will see in the following, the subleading corrections to $\Phi_c(n)$ and $S_c(n)$ (i.e. the functions $\mathcal{S}(n)$ is equation (16)) can also be obtained from the surviving subleading terms of $\mathbb{E}[M_c(n)]$ given in [11] (see also equations (68)–(70) below).

The outline of the paper is as follows. Section 2 is a reminder of some useful known results about the statistics of the maximum $M_c(t)$. The case of a 1D continuous-time Brownian motion with a constant drift $c$ is considered in section 2.1. Section 2.2 is devoted to 1D discrete-time random walks ($t = n \in \mathbb{N}$) with a constant drift $c$. The results of [11] giving the large $n$ asymptotic expansion of $\mathbb{E}[M_c(n)]$ are recalled, without demonstration, including all the terms surviving the large $n$ limit, for both random walks with $\mu = 2$ and Lévy flights with $1 < \mu < 2$. The relations given in equations (3) and (4) are derived in sections 3 and 4, respectively, first for a Brownian motion (sections 3.1 and 4.1), then in the case of random walks and Lévy flights (sections 3.2 and 4.2). In both cases, the large time asymptotic behavior of $\Phi_c(t)$ and $S_c(t)$ is obtained from the one of $\mathbb{E}[M_c(t)]$ as a function of the drift $c$. In section 4.3, we discuss and solve an apparent paradox about the first equality (4) linking the survival probability of the lamb in the lamb-lion problem to the total flux out of the system in the Smoluchowski problem. In section 5, we verify our analytical predictions via numerical simulations. Finally, we conclude in section 6.
2. Reminder of some useful results

In this section we briefly recapitulate some useful results from [11] about the statistics of the maximum of a 1D continuous-time Brownian motion and of 1D discrete-time random walks (and Lévy flights), both in the presence of a constant drift $c$.

2.1. 1D Brownian motion

First, we consider the case of a 1D Brownian motion. The interested reader is referred to the section 2 of [11] for details. Let $x(t)$ be a biased Brownian motion on a line starting from $x = 0$ at $t = 0$ and evolving according to equation (1). Write $M_c(t) = \max_{0 \leq \tau \leq t} \{x(\tau)\}$ the maximum of this process up to time $t$, where the subscript $c$ stands for the presence of the constant drift $c$ in equation (1). Let $Q_c(z, t) \equiv \text{Prob}[M_c(t) \leq z]$ denote the cumulative distribution of $M_c(t)$. Clearly, $Q_c(z, t)$ is also the probability that the Brownian trajectory stays below $z \geq 0$ up to time $t$. Define $y(t) = z - x(t)$ a Brownian motion with a drift $-c$ starting from $y = z$ at $t = 0$. Hence, $Q_c(z, t)$ is also the probability that the process $y(t)$ (with drift $-c$) stays positive (does not cross zero) up to time $t$. It is then easy to write a backward Fokker–Planck evolution for $Q_c(z, t)$ [17],

$$\frac{\partial Q_c(z, t)}{\partial t} = D \frac{\partial^2 Q_c(z, t)}{\partial z^2} - c \frac{\partial Q_c(z, t)}{\partial z},$$

valid for $z \geq 0$ with the boundary conditions

$$Q_c(z = 0, t) = 0; \quad \text{and} \quad Q_c(z \to \infty, t) = 1 \quad (17)$$

together with the initial condition

$$Q_c(z, t = 0) = 1 \quad \text{for} \quad z > 0. \quad (18)$$

This linear equation can be solved exactly. One finds,

$$Q_c(z, t) = \frac{1}{2} \left[ \text{erfc} \left( -\frac{z - ct}{\sqrt{4Dt}} \right) - e^{c z/D} \text{erfc} \left( \frac{z + ct}{\sqrt{4Dt}} \right) \right], \quad (19)$$

where \(\text{erfc}(x) = \frac{2}{\sqrt{\pi}} \int_{x}^{\infty} e^{-u^2} \, du\) is the complementary error function. It is easy to see from equation (20) that for $c > 0$, the cumulative distribution $Q_{c>0}(z,t)$ is always time-dependent, while for $c < 0$, it approaches a time-independent stationary distribution

$$Q_{c<0}(z, t) \xrightarrow{t \to \infty} 1 - \exp \left[ -\frac{|c| z}{D} \right]. \quad (21)$$

The PDF of $M_c(t)$ is the derivative $\partial_z Q_c(z, t)$, hence the expected maximum is given by $\mathbb{E}[M_c(t)] = \int_{0}^{+\infty} z \partial_z Q_c(z, t) \, dz$, which, via integration by parts, can be written as

$$\mathbb{E}[M_c(t)] = \int_{0}^{+\infty} [1 - Q_c(z, t)] \, dz. \quad (22)$$

From equation (22) and the result in equation (20), it is possible to compute the expected maximum $\mathbb{E}[M_c(t)]$. One gets an exact expression valid for all $c$ and all $t$, (see [11] for details)
\[ \mathbb{E}[M_c(t)] = \theta(c) \, ct + \sqrt{D \, t} \, G_2 \left( \frac{|c| \sqrt{t}}{\sqrt{D}} \right), \]

where the scaling function \( G_2(u) \) is exactly given by

\[ G_2(u) = \frac{4}{u \sqrt{\pi}} \int_0^{u/2} dv \left[ e^{-v^2} - \sqrt{\pi} \, v \operatorname{erfc}(v) \right] \]
\[ = \frac{1}{\sqrt{\pi}} \, e^{-u^2/4} + \frac{1}{u} \, \operatorname{erf} \left( \frac{u}{2} \right) - \frac{u}{2} \, \operatorname{erfc} \left( \frac{u}{2} \right), \]

with the asymptotics \( G_2(u) \to 2/\sqrt{\pi} \) as \( u \to 0 \) and \( G_2(u) \to 1/u \) as \( u \to \infty \). For \( c = 0 \) (no drift), equations (23) and (24) yield simply

\[ \mathbb{E}[M_0(t)] = \frac{2}{\sqrt{\pi}} \sqrt{D} t, \]

while for \( c \neq 0 \) and large \( t \), one finds

\[ \mathbb{E}[M_c(t)] \sim \theta(c) \, ct + \frac{D}{|c|} \quad (t \to \infty). \]

Thus, for a positive drift \( c > 0 \), the expected maximum increases linearly with \( t \) (with speed \( c \)), while for a negative drift \( c < 0 \), it approaches a constant \( D/|c| \) as \( t \to \infty \). The equations (25) and (26) coincide respectively with equations (5) and (6) in the introduction.

### 2.2. 1D Random walks and Lévy flights

Now, we consider the case of a 1D discrete-time random walk (including Lévy flights). The position \( x_n \) of the walker at step \( n \) evolves in discrete time step by the Markov rule (2), starting initially at \( x_0 = 0 \). Write \( M_c(n) = \max_{0 \leq m \leq n} \{ x_m \} \) the maximum of this process up to step \( n \), with \( n, m \in \mathbb{N} \) and where the subscript \( c \) stands for the presence of the constant drift \( c \) in equation (2). Like in the case of the Brownian motion, in the following we will need the evolution equation for the cumulative distribution \( Q_c(z, n) \equiv \text{Prob}[M_c(n) \leq z] \). To this end, we use the fact that \( Q_c(z, n) \) denotes the probability that the walker does not cross the level \( z \) up to step \( n \) and we define the process \( y_n = z - x_n \) with \( y_0 = z \). Thus, \( Q_c(z, n) \) is also the probability that the process \( y_n \), starting at \( y_0 = z \) and in the presence of a drift \( -c \), stays positive (does not cross zero) up to step \( n \). Given the evolution (2), it follows that \( y_n \) evolves via \( y_n = y_{n-1} - c - \eta_n \) and using the fact that \( \eta_n \) and \( -\eta_n \) have the same PDF \( f(\eta) \) (due to the symmetric nature of the noise), one finds that \( Q_c(z, n) \) satisfies the recursion relation

\[ Q_c(z, n) = \int_0^{+\infty} Q_c(z', n-1) \, f(z' - z + c) \, dz', \]

with the initial condition \( Q_c(z, 0) = 1 \) for all \( z \geq 0 \). The integral equation (27) is the discrete-time counterpart of the backward Fokker–Planck equation (17) for the Brownian motion. The relation between \( Q_c(z, n) \) and the expected maximum \( \mathbb{E}[M_c(n)] \) is of course the same as in the continuous-time setting (see equation (22)).
\[
\mathbb{E}[M_c(n)] = \int_0^{+\infty} [1 - Q_c(z, n)] \, dz.
\] (28)

The solution of the integral equation (27) for arbitrary \(f(\eta)\) is far from explicit and we will not use it to get \(\mathbb{E}[M_c(n)]\) from equation (28), unlike the line followed in the Brownian motion case. Nevertheless, as we will see in the next two sections, equations (27) and (28) are still crucial to derive the equations (3) and (4) relating \(\mathbb{E}[M_c(n)]\) to \(\Phi_c(n)\) and \(S_c(n)\).

Extracting the large \(n\) behavior of \(\mathbb{E}[M_c(n)]\) is a highly technical, non trivial, task that was carried out in [11, 26] by using a suitably generalized version of the Pollaczek–Spitzer formula, instead of trying to solve equation (27) directly. Here, we just recall the results without demonstration. The interested reader is referred to [11, 26] for details.

In the absence of a drift, \(c = 0\), Comtet and Majumdar found that for \(1 < \mu \leq 2\) and \(\nu > \mu + 1\) (see the remark below equation (10)), the large \(n\) behavior of \(\mathbb{E}[M_0(n)]\) is given by [26]

\[
\mathbb{E}[M_0(n)] = \frac{a\mu\Gamma(1 - 1/\mu)}{\pi} n^{1/\mu} + a\gamma + O\left(\frac{1}{n^{1-1/\mu}}\right) \quad (n \to +\infty),
\] (29)

with \(\gamma\) given in equation (10). In the presence of a drift, \(c \neq 0\), the large \(n\) behavior of \(\mathbb{E}[M_c(n)]\) depends on the value of the Lévy index \(\mu\). For \(1 < \mu < 2\), with \(\mu \neq 1 + 1/p\) for any integer \(p\), one finds [11]

\[
\mathbb{E}[M_c(n)] = \theta(c) cn + |c| \sum_{m=1}^{[1/(\mu - 1)]} \frac{C_m n 1 - m(\mu - 1)}{1 - m(\mu - 1)} + |c| \kappa_c + O\left(\frac{1}{n^{\mu - 1}}\right) \quad (n \to +\infty),
\] (30)

where \([1/(\mu - 1)]\) denotes the integer part of \(1/(\mu - 1)\), with

\[
C_m = (-1)^{m+1} \sin\left(\frac{m\pi\mu}{2}\right) \frac{\Gamma(m\mu - 1)}{\pi m!} \left(\frac{a}{|c|}\right)^{m\mu},
\] (31)

and where \(\kappa_c\) is a computable constant (see section 5.2 in [11] for details. Note that \(\kappa_c\) in equation (30) corresponds to \(\kappa_c + \Delta\kappa_c\) in [11]). For \(1 < \mu < 2\), with \(\mu = 1 + 1/p\) for some integer \(p\), one finds that the equation (30) must be replaced by [11]

\[
\mathbb{E}[M_c(n)] = \theta(c) cn + |c| \sum_{m=1}^{p-1} \frac{p C_m n 1 - m/p}{p - m} + |c| C_p \ln n + |c| \kappa_c + O\left(\frac{1}{n^{1/p}}\right) \quad (n \to +\infty).
\] (32)

Note that the leading terms in the equations (30) and (32) coincide with the asymptotics (13), as it should be. Finally, for \(\mu = 2\) one has [11]

\[
\mathbb{E}[M_c(n)] = \theta(c) cn + |c| \kappa_c + O\left(\frac{h(n)}{n^2} e^{-nI(|c|)}\right) \quad (n \to +\infty),
\] (33)

with \(\kappa_c\) given in equation (12), \(I(|c|) > 0\), and \(h(n)\) is subdominant with respect to the decaying exponential. Both \(I(x)\) and \(h(n)\) depends on the jump distribution \(f(\eta)\) and there is no generic expressions for these two functions. The large \(n\) behavior (33) coincides with the asymptotics (11).

From the results in equations (9) (for \(c = 0\)) and (11), (13) (for \(c \neq 0\)) it is clear that the two limits \(n \to \infty\) and \(c \to 0\) do not commute, hence the small \(c\) limit of the
large \( n \) behavior of \( \mathbb{E}[M_c(n)] \) is singular. This suggests the existence of a scaling regime describing the crossover between the leading large \( n \) behaviors of \( \mathbb{E}[M_c(n)] \) for \( c = 0 \) and a small nonzero \( c \). The corresponding scaling form has been determined in section 5.4 of [11]. One finds

\[
\mathbb{E}[M_c(n)] \sim \theta(c) \, cn + an^{1/\mu} \mathcal{G}_\mu \left( \frac{|c|}{a} \, n^{1-1/\mu} \right),
\]

with

\[
\mathcal{G}_\mu(u) = \frac{\mu}{\pi} u^{-\frac{1}{\mu-1}} \int_0^u dy \, y^{\frac{2-\mu}{\mu-1}} \int_0^{+\infty} dx \, f_{S,\mu}(x + y),
\]

where \( f_{S,\mu}(x) \) is the stable law of Lévy index \( \mu \). For \( \mu = 2 \), the stable law is the Gaussian distribution and one has \( f_{S,2}(x + y) = 1/(2\sqrt{\pi}) \, e^{-(x+y)^2/4} \). The right-hand side of (35) can then be computed explicitly, yielding \( \mathcal{G}_2(u) \) as given in equation (24) with \( \mathcal{G}_2(u) \sim 2/\sqrt{\pi} \) for \( u \to 0 \) and \( \mathcal{G}_2(u) \sim 1/u \) as \( u \to \infty \). For \( 1 < \mu < 2 \), there is no explicit expression of the scaling function but the small and large argument behaviors can still be obtained. In the small \( u \) limit, one has

\[
\mathcal{G}_\mu(u) \sim \frac{\mu}{\pi} \Gamma \left( 1 - \frac{1}{\mu} \right) \quad (u \to 0),
\]

while in the opposite large \( u \) limit, one gets

\[
\mathcal{G}_\mu(u) \sim \frac{\Gamma(\mu - 1)}{\pi(2 - \mu)} \sin \left( \frac{\pi \mu}{2} \right) \frac{1}{u^{\mu-1}} \quad (u \to +\infty).
\]

From these small and large argument behaviors of \( \mathcal{G}_\mu(u) \) one can check that the scaling form (34) reduces to the leading term of (9) for \( c = 0 \), and to equation (13) for \( 1 < \mu < 2 \) and \( c \neq 0 \), or equation (11) (with \( \kappa_c \) given in equation (12)) for \( \mu = 2 \) and a small nonzero \( c \).

We now have all what is needed to move on to the main new results of this paper; namely, establishing the relations (3) and (4) and obtaining the large time asymptotic behavior of \( \Phi_c(t) \) and \( S_c(t) \). This is the subject of the next two sections 3 and 4.

3. Smoluchowski flux problem in one dimension

3.1. Continuous flux to a trap (Brownian motion)

Consider a semi-infinite line \( z \in [0, \infty) \) with a single immobile trap, or absorber, at the origin \( z = 0 \). Initially, the full semi-infinite line to the right of the trap is filled uniformly by non-interacting particles with constant density \( \rho_0 \) (see figure 1). For \( t > 0 \), the particles perform i.i.d. Brownian motions with a constant drift \( c \), like in equation (1) (with a different starting position at \( t = 0 \) for each particle). When a particle hits the trap at the origin, it gets absorbed there. Let \( \rho_c(z, t) \), for \( z \geq 0 \), denote the density profile at time \( t \), starting from a flat profile \( \rho_c(0, 0) = \rho_0 \) (for \( z > 0 \)) at \( t = 0 \). How does the density profile \( \rho_c(z, t) \) evolve with time \( t \)? This is the 1D version of the
celebrated Smoluchowski problem [12]. Smoluchowski was also interested in the net flux $\Phi_c(t)$ out of the system up to time $t$ [12, 18, 28–30]. Clearly,

$$
\Phi_c(t) = \int_0^{\infty} [\rho_0 - \rho_c(z,t)] \, dz,
$$

(38)

counts the net flux out of the system up to time $t$ through both boundaries at $z = 0$ and $z = \infty$. (Note that at the formal boundary $z = \infty$, particles can go both in and out of the system, unlike the boundary at $z = 0$ where they only go out). The density profile $\rho_c(z,t)$ evolves via the biased diffusion equation [18]

$$
\frac{\partial \rho_c(z,t)}{\partial t} = D \frac{\partial^2 \rho_c(z,t)}{\partial z^2} - c \frac{\partial \rho_c(z,t)}{\partial z},
$$

(39)

with boundary conditions $\rho_c(z=0,t) = 0$ and $\rho_c(z \to \infty, t) = \rho_0$, starting from the initial condition $\rho_c(z,t=0) = \rho_0$ for all $z > 0$. By comparing this evolution equation to equation (17) and the associated boundary and initial conditions (18) and (19), it follows immediately that

$$
\rho_c(z,t) = \rho_0 Q_c(z,t),
$$

(40)

where $Q_c(z,t)$ is given in equation (20). Figure 2 shows plots of $\rho_c(z,t)$ in equation (40) as a function of $z$ at different $t$ for both positive and negative $c$. From this equation (40), we see that the Brownian particle density $\rho_c(z,t)$ in the Smoluchowski problem is somewhat unexpectedly related to the cumulative distribution of the maximum of a single Brownian motion starting at the origin. Using then equation (40) on the right-hand side of equation (38), one obtains

$$
\Phi_c(t) = \rho_0 \int_0^{\infty} [1 - Q_c(z,t)] \, dz = \rho_0 \mathbb{E}[M_c(t)],
$$

(41)
where we have used the expression (22) of $\mathbb{E}[M_c(t)]$. Thus, the net flux $\Phi_c(t)$ coincides with the expected maximum $\mathbb{E}[M_c(t)]$ up to a constant factor $\rho_0$, which proves the relation (3).

From equations (23) and (41) one gets an exact expression of $\Phi_c(t)$ valid for all $c$ and $t$,

$$\Phi_c(t) = \rho_0 \theta(c) t + \rho_0 \sqrt{D t} G_2 \left( \frac{|c| \sqrt{t}}{\sqrt{D}} \right).$$

(42)

In particular, using the behaviors of $\mathbb{E}[M_c(t)]$ in equations (25) and (26), one obtains

$$\Phi_c(t) \sim \begin{cases} 
\rho_0 D / |c|, & c < 0 \\
2 \rho_0 \sqrt{D t / \pi}, & c = 0 \\
\rho_0 c t, & c > 0 
\end{cases} \quad (t \to \infty).$$

(43)

At first sight, in may seem a bit confusing that for $c > 0$ the net flux out of the system increases linearly with $t$. This is simply due to the fact that $\Phi_c(t)$ includes contributions from both boundaries at $z = 0$ and $z = \infty$. Hence, the net flux out of the system is not only through the origin but also ‘through infinity’. The dominant linear growth of $\Phi_c(t)$ for $c > 0$ comes from the contribution of the boundary at $z = \infty$ (i.e. the outgoing flux ‘through infinity’). To make it clearer, it can be useful to give another, more transparent, derivation of the flux by integrating over the instantaneous current. To this end we first rewrite equation (39) as a continuity equation

$$\frac{\partial \rho_c(z, t)}{\partial t} + \frac{\partial j_c(z, t)}{\partial z} = 0,$$

(44)

where the instantaneous current through $z$ (to the right) is

$$j_c(z, t) = -D \frac{\partial \rho_c(z, t)}{\partial z} + c \rho_c(z, t).$$

(45)

The flux out of the system through $z = 0$ up to time $t$ is $- \int_0^t j_c(0, \tau) \, d\tau$ and the flux out of the system ‘through infinity’ up to time $t$ is $\int_0^t j_c(z = \infty, \tau) \, d\tau$. Hence, the net flux out of the system up to time $t$ is simply given by

$$\Phi_c(t) = - \int_0^t j_c(0, \tau) \, d\tau + \int_0^t j_c(z = \infty, \tau) \, d\tau,$$

(46)

which is equivalent to equation (38) with the advantage of making explicit the contributions from both boundaries at $z = 0$ and $z = \infty$. Now, for the Brownian case considered in this section, we can evaluate the individual fluxes through $z = 0$ and $z = \infty$ by using equation (40) and the explicit solution in equation (20). After some straightforward algebra one finds, for any $c$,

$$- \int_0^t j_c(0, \tau) \, d\tau = \rho_0 \sqrt{D t} G_2 \left( \frac{c \sqrt{t}}{\sqrt{D}} \right),$$

(47)

https://doi.org/10.1088/1742-5468/ab35e5
where $G_2(u)$ is given in equation (24), and
\[
\int_0^t j_c(z \to \infty, \tau) \, d\tau = \rho_0 c t. \tag{48}
\]

Injecting (47) and (48) onto the right-hand side of (46) yields
\[
\Phi_c(t) = \rho_0 c t + \rho_0 \sqrt{D} t \, G_2 \left( \frac{c \sqrt{t}}{\sqrt{D}} \right), \tag{49}
\]
which is exactly the same as equation (42) (it can be checked for positive and negative $c$, using the relation $G_2(-u) = u + G_2(u)$ in the latter case). For $c > 0$ and $t \to \infty$, the dominant linear growth of $\Phi_c(t)$ in the third line of equation (43) corresponds clearly to the outgoing flux ‘through infinity’ in equation (48). The fact that $\Phi_c(t)$ includes contributions from both boundaries at $z = 0$ and $z = \infty$ is important and should be borne in mind to understand results that may seem paradoxical at first sight. We will get back to this point in a more general setting in section 4.3.

### 3.2. Discrete flux to a trap (random walks and Lévy flights)

We now consider the same problem as above except that the particles perform i.i.d. discrete-time Markov jump processes (instead of Brownian motions), in the presence of a constant drift $c$, each evolving via equation (2). When a particle makes a jump to the negative side $z < 0$, it gets absorbed by the trap. Let $\rho_c(z, n)$ denote the density profile at step $n$, starting from $\rho_c(z, 0) = \rho_0$. The discrete-time counterpart of equation (38) reads
\[
\Phi_c(n) = \int_{0}^{+\infty} [\rho_0 - \rho_c(z, n)] \, dz, \tag{50}
\]
where, as above, $\Phi_c(n)$ counts the net average number of particles that have left the system up to step $n$ (through both boundaries at 0 and $\infty$). One can easily write down the following recursion relation,
\[
\rho_c(z, n) = \int_{0}^{+\infty} \rho_c(z', n - 1) \, f(z' - z + c) \, dz', \tag{51}
\]
where we have used $f(\eta) = f(-\eta)$, and with initial condition $\rho_c(z, 0) = \rho_0$. The equation (51) is the discrete-time counterpart of the diffusion equation (39) in the Brownian motion case. Comparing equations (51) and (27), and their associated initial conditions, one obtains
\[
\rho_c(z, n) = \rho_0 \, Q_c(z, n), \tag{52}
\]
which, together with equations (50) and (28), yields
\[
\Phi_c(n) = \rho_0 \int_{0}^{+\infty} [1 - Q_c(z, n)] \, dz = \rho_0 \, \mathbb{E}[M_c(n)]. \tag{53}
\]
This result enlarges the validity of the relation (3) from continuous-time Brownian motion to discrete-time random walks.
Now, from the equation (53) and the large $n$ expressions of $\mathbb{E}[M_n(c)]$ given in section 2.2 one can easily obtain the large $n$ behavior of $\Phi_c(n)$. In particular, the leading behavior of $\mathbb{E}[M_n(c)]$ in equation (34) gives the leading behavior of $\Phi_c(n)$ as

$$
\Phi_c(n) \sim \rho_0 \theta(c) c n + \rho_0 an^{1/\mu} \mathcal{G}_\mu \left( \frac{|c|}{a} n^{1-1/\mu} \right),
$$

(54)

and, from the large and small argument behaviors of the scaling function $\mathcal{G}_\mu(u)$, one has

$$
\Phi_c(n) \sim \begin{cases} 
\rho_0 a^2/|c|, & c < 0 \\
2 \rho_0 a \sqrt{n/\pi}, & c = 0 \\
\rho_0 cn, & c > 0
\end{cases} \quad (n \to \infty),
$$

(55)

for $\mu = 2$, and

$$
\Phi_c(n) \sim \begin{cases} 
|c| \rho_0 C n^{2-\mu}/(2-\mu), & c < 0 \\
\rho_0 n^{1/\mu} \Gamma(1-1/\mu) n^{1/\mu}/\pi, & c = 0 \\
\rho_0 cn, & c > 0
\end{cases} \quad (n \to \infty),
$$

(56)

for $1 < \mu < 2$, where the constant $C$ is given in equation (14).

4. Survival probability of the trap in one dimension: the lamb-lion problem

An other interesting question coming up in the setting of the Smoluchowski problem is the determination of the survival probability of the trap, $S_c(t)$, up to time $t$ (with either $t \in \mathbb{R}^+$ or $t = n \in \mathbb{N}$). More precisely, $S_c(t)$ is the probability that none of the particles, initially uniformly distributed with density $\rho_0$, has hit the origin up to time $t$. This problem is sometimes referred to in the literature as the lamb-lion problem [18]: a lamb is immobile at the origin $z = 0$, while $N$ lions with initial positions uniformly distributed over the interval $z \in [0, L]$ undergo independent Brownian motions (or random walks) with a constant drift $c$ (see figure 1). In the thermodynamic limit $L, N \to +\infty$ keeping $\rho_0 = N/L$ fixed, $S_c(t)$ is the survival probability of the lamb up to time $t$.

Let $S_c(t|N, L)$ denote the survival probability of the lamb up to time $t$ for given $N$ and $L$, and write $q_c(z_i, t)$ the probability that the $i$th lion, starting initially at $z_i \in [0, L]$, does not reach the lamb up to time $t$. Since the lions move independently from each other, one clearly has

$$
S_c(t|N, L) = \left\langle \prod_{i=1}^N q_c(z_i, t) \right\rangle = \prod_{i=1}^N \left[ \frac{1}{L} \int_0^L q_c(z_i, t) \, dz_i \right] \tag{57}
$$

$$
= \left[ \frac{1}{L} \int_0^L q_c(z, t) \, dz \right]^N = \left[ 1 - \frac{1}{L} \int_0^L (1 - q_c(z, t)) \, dz \right]^N
$$

where $\langle \cdot \rangle$ denotes the average over the $z_i$’s uniformly and independently distributed in $[0, L]$. Taking then the thermodynamic limit, $L, N \to +\infty$ with fixed $\rho_0 = N/L$, one gets

https://doi.org/10.1088/1742-5468/ab35e5

15
\[
S_c(t) = \lim_{L \to +\infty} S_c(t) = \exp \left[ -\rho_0 \int_0^{+\infty} (1 - q_c(z, t)) \, dz \right].
\] (58)

It remains to compute \( q_c(z, t) \), which is done differently depending on whether the lions perform continuous-time Brownian motions or discrete-time random walks (or Lévy flights).

4.1. Continuous-time Brownian motions

In the case of Brownian motions, it is well known that \( q_c(z, t) \) satisfies the backward Fokker–Planck equation \([17]\)
\[
\frac{\partial q_c(z, t)}{\partial t} = D \frac{\partial^2 q_c(z, t)}{\partial z^2} + c \frac{\partial q_c(z, t)}{\partial z},
\] (59)
valid for \( z \geq 0 \) with the boundary and initial conditions \( q_c(0, t) = 0, \ q_c(z \to \infty, t) = 1 \), and \( q_c(z, 0) = 1 \) for all \( z > 0 \). This is exactly the same equation as equation \((17)\), with the same boundary and initial conditions, in which \( c \) is replaced with \(-c\). It follows immediately that
\[
q_c(z, t) = Q_{-c}(z, t),
\] (60)
with \( Q_c(z, t) \) given in equation \((20)\). Injecting \((60)\) into \((58)\) and using the equation \((41)\), one finds
\[
S_c(t) = \exp \left[ -\Phi_{-c}(t) \right] = \exp \left[ -\rho_0 E[M_{-c}(t)] \right],
\] (61)
which proves the relation \((4)\) in the Brownian motion setting. From equations \((23)\) and \((61)\) one gets an exact expression of \( S_c(t) \) valid for all \( c \) and \( t \),
\[
S_c(t) = \exp \left[ \rho_0 \theta(-c) c t - \rho_0 \sqrt{D t} G_2 \left( \frac{|c| \sqrt{t}}{\sqrt{D}} \right) \right],
\] (62)
which, in the large time limit, reduces to
\[
S_c(t) \sim \begin{cases} 
K_{BM} \exp \left( -\rho_0 |c| t \right), & c < 0 \\ 
\exp \left( -\frac{2\pi}{\sqrt{D}} \sqrt{D t} \right), & c = 0 \quad (t \to \infty), \\ 
K_{BM}, & c > 0 
\end{cases}
\] (63)
where \( K_{BM} = \exp(-D\rho_0/|c|) \). It follows in particular that if \( c > 0 \) then the lamb will survive with a finite probability as \( t \to \infty \).

4.2. Generalisation to discrete-time random walks and Lévy flights

In the case of discrete-time random walks evolving via equation \((2)\), the time evolution of \( q_c(z, n) \) is given by the recursion relation \([17]\)
\[
q_c(z, n) = \int_0^{+\infty} q_c(z', n - 1) f(z' - z - c) \, dz',
\] (64)
with the initial condition \( q_c(z, 0) = 1 \) for all \( z \geq 0 \). This integral equation is the discrete-time counterpart of the continuous-time backward Fokker–Planck equation \((59)\). It is

https://doi.org/10.1088/1742-5468/ab35e5

16
readily seen that the equation (64) for \( q_c(z,n) \) is exactly the same as the one for \( Q_{-c}(z,n) \), equation (27) with the same initial condition and \( c \) replaced with \(-c\). It thus follows immediately that

\[
q_c(z,n) = Q_{-c}(z,n).
\]  

(65)

Finally, injecting (65) into (58), with \( t = n \in \mathbb{N} \), and using the equation (53), one obtains

\[
S_c(n) = \exp \left[ -\Phi_{-c}(n) \right] = \exp \left[ -\rho_0 \mathbb{E}[M_{-c}(n)] \right],
\]  

(66)

which proves the relation (4) for discrete-time random walks.

In the large \( n \) limit, the leading exponential behavior of \( S_c(n) \) is correctly obtained by replacing \( \mathbb{E}[M_{-c}(n)] \) with the scaling form (34), but it misses the slowly varying prefactor associated with the subdominant corrections to \( \mathbb{E}[M_{-c}(n)] \), as these corrections do not appear in equation (34). Note that knowing this prefactor is important because it can contribute significantly to the order of magnitude of \( S_c(n) \) when \( n \) is large. For \( \mu = 2 \) the prefactor is found to reduce to a mere constant and, according to equations (29) and (33), one has

\[
S_c(n) \sim \begin{cases} 
K_{RW} \exp \left(-\rho_0|c|n\right), & c < 0 \\
K_{RW}^{(0)} \exp \left(-\frac{2a\rho_0}{\sqrt{\pi}} \sqrt{n}\right), & c = 0 \\
K_{RW}, & c > 0
\end{cases} \quad (n \to \infty),
\]  

(67)

as announced in equation (15), where \( K_{RW}^{(0)} = \exp(-a\rho_0\gamma) \) with \( \gamma \) given by equation (10), and \( K_{RW} = \exp(-|c|/\rho_0\kappa_c) \) with \( \kappa_c \) given by equation (12) (note that \( \kappa_{-c} = \kappa_c \)). For \( 1 < \mu < 2 \), the large \( n \) behavior of \( S_c(n) \) is obtained by using the equations (29) and (30), or (32) on the right-hand side of (66). Let \( \mathcal{J}_>(n) \) and \( \mathcal{J}_<(n) \) be defined respectively by

\[
\ln \mathcal{J}_>(n) = -\rho_0|c| \sum_{m=2}^{\left[1/(\mu-1)\right]} \frac{C_m n^{1-m(\mu-1)}}{1-m(\mu-1)} - \rho_0|c|\kappa_c,
\]  

(68)

if \( \mu \neq 1 + 1/p \) for any integer \( p \),

\[
\ln \mathcal{J}_>(n) = -\rho_0|c| \sum_{m=2}^{\frac{p-1}{m}} \frac{\rho C_m n^{1-m/p}}{p-m} - \rho_0|c|C_p \ln n - \rho_0|c|\kappa_c,
\]  

(69)

if \( \mu = 1 + 1/p \) for some integer \( p \), and

\[
\mathcal{J}_<(n) = \mathcal{J}_>(n) \exp \left(-\frac{|c|\rho_0 C}{2-\mu} n^{2-\mu}\right).
\]  

(70)

We recall that the constants \( C \) and \( C_m \) are given in equations (14) and (31) respectively. Bringing out the leading exponential behavior of \( S_c(n) \), one finds

\[
S_c(n) \sim \begin{cases} 
\mathcal{J}_c(n) \exp \left(-\rho_0|c|n\right), & c < 0 \\
K_{RW}^{(0)} \exp \left(-\frac{2a\rho_0\Gamma(1-\mu)}{\pi} n^{1/\mu}\right), & c = 0 \\
\mathcal{J}_>(n) \exp \left(-\frac{c\rho_0 C}{2-\mu} n^{2-\mu}\right), & c > 0
\end{cases} \quad (n \to \infty),
\]  

(71)
as announced in equation (16), where the prefactors $\mathcal{S}_<(n)$ and $\mathcal{S}_>(n)$ are slowly varying compared with the exponential of $n$ and $n^{2-\mu}$, respectively (see equations (70) and (69)). Note that the numerical value of the constant $K_{rw}$ in equation (71) is not the same as in equation (67), as $\gamma$ in equation (10) depends on $\mu$. As explained in the introduction, an interesting, and a bit counterintuitive, consequence of this result is that the survival probability of the lamb still decays to zero in the presence of a positive drift, unlike in the $\mu = 2$ case where it goes to a constant, as can be seen in the third line of equation (71). Such a decrease of $S_c(n)$ for $c > 0$ and $1 < \mu < 2$ is to be attributed to the fact that, sooner or later, lions undergoing Lévy flights will always perform rare big jumps that will overcompensate for their linear drift away from the lamb.

4.3. An apparent paradox

We end this section with the following interesting observation. The relation $S_c(t) = \exp[-\Phi_c(t)]$ (with $t \in \mathbb{R}^+$ or $t = n \in \mathbb{N}$) indicates that the survival probability of the lamb depends on the total net flux of lions out of the system, i.e. through both boundaries at $z = 0$ and $z = \infty$. On the other hand, intuitively one expects the survival probability to depend on the flux of lions through the origin only, where the immobile lamb is located. Although seemingly paradoxical, it can be shown that, actually, there is no contradiction whatsoever, as we will now see. Below, we will use the word ‘particles’ for both particles in the Smoluchowski problem and lions in the lamb-lion problem. Before resolving the (apparent) contradiction, define $\phi_c(z_0, t) = -\int_0^t j_c(z_0, \tau) d\tau$ where $j_c(z_0, \tau)$ denotes the instantaneous current of particles through $z = z_0$ counted algebraically. More precisely, $\phi_c(z_0, t)$ is the average number of particles that have crossed $z = z_0$ from $z > z_0$ to $z < z_0$ minus the average number of particles that have crossed $z = z_0$ from $z < z_0$ to $z > z_0$, up to time $t$. Note that, since no particle enters the system at $z = 0$ (from the negative side), $\phi_c(0, t)$ reduces to the average number of particles that have passed through the origin (to the negative side), up to time $t$.

First we prove that $S_c(t)$ does depend on $\phi_c(0, t)$ only, as expected. Clearly, the probability for a given particle starting at some $z > 0$ to cross the origin before time $t$ is $1 - q_c(z, t)$. Now, the average number of particles initially in $[z, z + dz]$ is $\rho_0 dz$ and $\rho_0(1 - q_c(z, t)) dz$ gives the average number of particles initially in $[z, z + dz]$ that have crossed the origin before time $t$. Hence, integrating over the initial position of the particles gives the average number of particles that have crossed the origin up to time $t$,

$$\phi_c(0, t) = \rho_0 \int_0^{+\infty} \left[1 - q_c(z, t)\right] dz. \quad (72)$$

Consequently, putting (72) on the right-hand side of equation (58), one obtains

$$S_c(t) = \exp[-\phi_c(0, t)]. \quad (73)$$

This relation is the one we should expect intuitively. Indeed, the passage of particles through the origin forms a Poisson process of parameter $\phi_c(0, t)$ and the probability that no particle has passed through the origin up to time $t$ is just $\exp[-\phi_c(0, t)]$. Comparing the equation (73) with $S_c(t) = \exp[-\Phi_c(t)]$ in equation (4) leads to a non-trivial relation.
\[ \Phi_-(t) = \phi_c(0, t), \]  
which is thus necessary to resolve the above-mentioned apparent contradiction. Changing the sign of \( c \) from one side of equation (74) to the other is crucial. Clearly, \( \Phi_c(t) \neq \phi_c(0, t) \), and we would have to face a real contradiction if there was no such a change of sign.

It remains to prove the identity (74). To this end, we use the relation

\[ \mathbb{E}[M_-(t)] = \mathbb{E}[M_c(t)] - ct, \]  
discussed at the end of the introduction in [11] for \( t = n \in \mathbb{N} \) and valid also for \( t \in \mathbb{R}^+ \). (The reasoning leading to (75) in [11] is quite general and it can be transposed straightforwardly to the case of continuous-time processes). From equations (3) and (75) one gets

\[ \Phi_-(t) = \Phi_c(t) - \rho_0 ct = \phi_c(0, t) - \phi_c(z \to \infty, t) - \rho_0 ct, \]  
where we have written \( \Phi_c(t) \) as \( \Phi_c(t) = \phi_c(0, t) - \phi_c(z \to \infty, t) \). Let us now estimate \( \phi_c(z \to \infty, t) \). This is precisely given by

\[ \phi_c(z \to \infty, t) = -\int_0^t j_c(z \to \infty, \tau) \, d\tau \]  
where \( j_c(z \to \infty, \tau) \) is the instantaneous current at large \( z \). Using the fact that the particles very far from the absorbing boundary do not feel the presence of the boundary, we see that, as \( z \to \infty \), the particle density profile goes to the initial flat one with density \( \rho_0 \) and the average particle velocity goes to the drift \( c \), from which it follows that \( j_c(z \to \infty, t) = c \rho_0 \). Hence, integrating over time this instantaneous current in equation (77), we get \( \phi_c(z \to \infty, t) = -\rho_0 c t \) which generalizes the Brownian motion result in equation (48). Putting this result on the right-hand side of equation (76) yields \( \Phi_-(t) = \phi_c(0, t) \), which proves the relation (74).

### 5. Numerical simulations

We have compared our analytical results with numerical simulations. For this purpose, we have simulated \( N \) random walks with a drift evolving via equation (2). Initially, the \( N \) walkers are uniformly distributed over the interval \([0, L]\) with a uniform density \( \rho_0 \). To compare with our results we have to consider the limit \( N, L \to \infty \) with \( \rho_0 = N/L \) fixed. In the simulations presented here, we have taken \( N = L = 10^4 \), corresponding to \( \rho_0 = 1 \). We have first checked our predictions for the Smoluchovski problem and computed the flux of particles \( \Phi_c(n) \) out of the system. We have checked the exact identity \( \Phi_c(n) = \rho_0 \mathbb{E}[M_c(n)] \). Hence our numerical results for \( \Phi_c(n) \) reproduce the ones obtained previously for \( \mathbb{E}[M_c(n)] \) in [11] exactly. Therefore, we do not not show them again here and referred the interested reader to the section 6 of [11]. Instead, in this section we present our numerical results for the survival probability \( S_c(n) \).

https://doi.org/10.1088/1742-5468/ab35e5
Figure 3. (a) Plot of the survival probability $S_c(n)$ as a function of $n$ for particles/lions performing a Gaussian random walk with unit variance $\sigma = 1$ (hence $\mu = 2$) and with a drift $c = 1$. The blue squares show the results obtained by simulating $N = 10^4$ random walks with a uniform density $\rho_0 = 1$. The solid line corresponds to our theoretical prediction given in the third line of equation (15), i.e. $S_c(n \to \infty) \to K_{RW} = 0.881286 \ldots$ (b) Plot of $-\log[S_c(n)]$ as a function of $n$, on a log–log plot, for Lévy flights with $\mu = 7/4$ and drift $c = 1$. Here also the blue squares show the results obtained by simulating $N = 10^4$ random walks with a uniform density $\rho_0 = 1$ while the solid line corresponds to the leading behavior as predicted by the third line of equation (16), i.e. $-\log[S_c(n)] \approx c\rho_0 C/(2 - \mu)n^{2-\mu}$ with $C$ given in (14). A comparison of these two plots (a) and (b) clearly shows that $S_c(t)$ is much smaller for Lévy flights with $\mu < 2$ than for standard random walks (with $\mu = 2$).

The case $c > 0$. In the left panel of figure 3 we show a plot of our numerical data obtained for $S_c(n)$ for the Gaussian random walk, i.e. for a random walk (2) with a Gaussian jump distribution $f(\eta)$ with variance $\sigma = 1$, thus corresponding to a Lévy index $\mu = 2$, and with a drift $c = 1$. In this case, the constant $\kappa_c$ entering the definition of the amplitude $K_{RW} = \exp(-|c|\rho_0\kappa_c)$ in equation (15) is given by the expression [11]

$$\kappa_c = \sum_{m=1}^{\infty} \left[ \frac{e^{-t^2m}}{2b\sqrt{\pi m}} - \frac{1}{2} \text{erfc}(b\sqrt{m}) \right],$$

where $b = |c|/\sigma\sqrt{2}$ and $\text{erfc}(z) = 2/\sqrt{\pi} \int_z^{\infty} e^{-t^2} \, dt$. On the left panel of figure 3, we see that $S_c(n \to \infty) \approx K_{RW}$ for $n \gtrsim 10$ steps, in agreement with our predictions in the third line of equation (15). In addition, the numerical value of $K_{RW}$ is also found to be in very good agreement with the theoretical one: for $c = 1$ and $\sigma = 1$, one has $\kappa_c = 0.126373 \ldots$, which gives $K_{RW} = 0.881286 \ldots$ for $\rho_0 = 1$. In the right panel of figure 3 we show a plot of $-\log[S_c(n)]$ as a function of $n$ for a Lévy flight of index $\mu = 7/4$. From our analytical predictions in the third line of equation (16) one expects that, for large $n$, $-\log[S_c(n)] \approx c\rho_0 C/(2 - \mu)n^{2-\mu} + o(n^{2-\mu})$.
Smoluchowski flux and lamb-lion problems for random walks and Lévy flights with a constant drift

where the constant $C$ is given in equation (14). This leading behavior is indicated as a solid line in figure 3 and we see that the agreement with our numerical data is quite good for $n \gtrsim 100$.

The case $c < 0$. In the left panel of figure 4 we show a plot of our numerical data obtained for $S_c(n)$ for the same Gaussian random walk as in the case of the left panel of figure 3 ($\mu = 2$) but now with a negative drift $c = -1/4$. Comparing these data with our theoretical prediction given in the first line of equation (15), i.e. $S_c(n) \approx K_{RW} \exp(-|c|n)$ with $K_{RW} = 0.228255\ldots$ (b) Plot of $S_c(n)$ as a function of $n$ (on a semi-log scale) for Lévy flights with $\mu = 7/4$ and drift $c = -1/4$. Here also the blue squares show the results obtained by simulating $N = 10^4$ random walks with a uniform density $\rho_0 = 1$ while the solid line corresponds to the leading behavior as predicted by the first line of equation (16), i.e. $S_c(n) \approx \exp(-|c|\rho_0 n - |c|\rho_0 C/(2 - \mu)n^{2-\mu})$ with $C$ given in (14).

6. Conclusion

In this paper, we have generalized the Smoluchowski flux and the lamb-lion problems, well studied for Brownian motion, to discrete-time random walks/Lévy flights with a constant drift. Specifically, we have considered the problem of independent particles performing 1D random walks or Lévy flights, with Lévy index $1 < \mu \leq 2$ and a constant

https://doi.org/10.1088/1742-5468/ab35e5

21
drift $c$, in the presence of an absorbing immobile trap (or lamb) at the origin. Initially these particles are uniformly distributed over the positive real axis with density $\rho_0$. We have obtained exact results for the net flux $\Phi_c(n)$ of particles out of the system (Smoluchowski problem) and for the survival probability $S_c(n)$ of the trap or lamb after $n$ steps (lamb-lion problem). After deriving the important relations $\Phi_c(n) = \rho_0 \mathbb{E}[M_c(n)]$ and $S_c(n) = \exp[-\Phi_{-c}(n)]$ linking $\Phi_c(n)$ and $S_c(n)$ to the expected value $\mathbb{E}[M_c(n)]$ of the maximum of a single random walker in the presence of a drift $c$, we have used our recently obtained exact results for $\mathbb{E}[M_c(n)]$ in the large $n$ limit [11]. We have found in particular that, for lions undergoing independent Lévy flights ($1 < \mu < 2$), the survival probability of the lamb still decays to zero even in the presence of a positive drift ($c > 0$). More precisely, one has $S_{c>0}(n \to \infty) \approx \exp(-\lambda n^{2-\mu})$ for $1 < \mu < 2$, where $\lambda$ is a $\mu$-dependent positive constant, while $S_{c>0}(n \to \infty) \to K_{RW} > 0$ for standard random walks (i.e. with $\mu = 2$). This somewhat counterintuitive result follows from the fact that lions undergoing Lévy flights will always perform rare big jumps that will overcompensate for their linear drift away from the lamb. We have checked that our analytical results are confirmed by numerical simulations.

Note that, in this paper, we have restricted ourselves to the lamb-lion and Smoluchowski flux problem for Lévy flights with Lévy index $1 < \mu \leq 2$. In this case, the expected maximum $\mathbb{E}[M_c(n)]$ after $n$ steps is finite for any finite $n$. Consequently, the thermodynamic limit $L \to \infty$, $N \to \infty$ with fixed density $\rho_0 = N/L$ exists and gives us a well defined survival probability or total flux in this thermodynamic limit. One may naturally wonder what happens if the Lévy index $\mu$ is in the range $0 < \mu \leq 1$. In this case, the expected maximum $\mathbb{E}[M_c(n)]$ is infinite for any finite $n$, even though there is a normalized distribution for the maximum $M_c(n)$ up to $n$ steps. If one follows the same analysis presented in this paper, e.g. for the lamb-lion problem, one sees that the thermodynamic limit does not exist. Indeed, for $0 < \mu < 1$, one finds that the survival probability $S_c(n)$ of the lamb up to $n$ steps behaves, for large $L$ and large $N$ with fixed $\rho_0 = N/L$, as $S_c(n) \sim e^{-\lambda n^{1-\mu}}$ for large $n$. Thus the asymptotic large $n$ results still depends on $L$, as $L \to \infty$, unlike in the case $1 < \mu \leq 2$.

The present work provides an example of interesting physical applications of extreme value statistics of random walks and Lévy flights. For discrete time random walks/ Lévy flights, this extreme value statistics problem is surprisingly very hard, though several exact analytical results have been obtained recently [11, 31, 32]. It would be interesting to find other applications of these results. For instance, in the absence of a drift (i.e. $c = 0$), the statistical properties of the convex hull a two-dimensional random walk (or Brownian motion) can be computed from the extreme value statistics of the corresponding 1D random walk (or Brownian motion) [27, 33–35]. The next step could be to extend these results and study the convex hull of random walks or Brownian motion in the presence of a drift $c \neq 0$.

An other natural continuation of this work would be to extend the results of this paper to other stochastic processes like, e.g. persistent random walks, i.e. particles performing ‘run and tumble’ dynamics which are currently widely studied in the context of active matter (see e.g. [36, 37]). Recently, the dynamics of such run and tumble particles in semi-infinite domains have been worked out [38–42] and it would be interesting to extend the present studies to the case of these active particles.
