Abstract

HD 49798 is a binary system consisting of a hot and bright subdwarf in a 1.55 day orbit with a compact companion. At the time of its discovery and classification, it was the brightest hot subdwarf known (Jaschek & Jaschek 1963), and remains one of the brightest today (Mereghetti et al. 2011). It was initially known to be a binary system, but Thackeray (1970) was the first to give a spectroscopic orbital period of 1.5477 days and to suggest that the compact companion may be a WD. Just two years later, Dufton (1972) performed a non-local thermodynamical equilibrium (LTE) analysis to derive estimates on the effective temperature ($T_{\text{eff}}$) and the surface gravity ($\log g$) of the subdwarf, and found $T_{\text{eff}} \approx 45,500 \pm 2000$ K, $\log g \approx 4.25 \pm 0.2$, $y = 50^{+10}_{-5}$

Key words: binaries: close stars; magnetars; subdwarfs; supernovae; general - X-rays: binaries

1. Introduction

HD 49798 is a binary system consisting of a hot and bright subdwarf in a 1.55 day orbit with a compact companion. At the time of its discovery and classification, it was the brightest hot subdwarf known (Jaschek & Jaschek 1963), and remains one of the brightest today (Mereghetti et al. 2011). It was initially known to be a binary system, but Thackeray (1970) was the first to give a spectroscopic orbital period of 1.5477 days and to suggest that the compact companion may be a WD. Just two years later, Dufton (1972) performed a non-local thermodynamical equilibrium (LTE) analysis to derive estimates on the effective temperature ($T_{\text{eff}}$) and the surface gravity ($\log g$) of the subdwarf, and found $T_{\text{eff}} \approx 45,500 \pm 2000$ K, $\log g \approx 4.25 \pm 0.2$, $y = 50^{+10}_{-5}$

In this study, we build stellar models that match the measured values of $T_{\text{eff}}$, $\log g$, mass, and surface abundances of the subdwarf and constrain the past and future evolution of this system using MESA version 8118 (Paxton et al. 2011, 2013, 2015).

2. Observational Analysis

In this study, we build stellar models that match the measured values of $T_{\text{eff}}$, $\log g$, mass, and surface abundances of the subdwarf and constrain the past and future evolution of this system using MESA version 8118 (Paxton et al. 2011, 2013, 2015).

2.1. Previous Compact Object Interpretation

Bisscheroux et al. (1997) looked at the same X-ray data from ROSAT as Israel et al. (1996), but used different estimates for the wind mass loss rates from the subdwarf and concluded that a WD is more likely, but, an NS cannot be ruled out. One of their arguments against an NS companion has to do with their low birthrate and the small likelihood of seeing such a system. This argument does not hold because in the alternative scenario, a WD companion would accrete enough mass to reach $M_{\text{crit}}$, or a solitary millisecond pulsar (MSP).

Several papers from the same group have been published on this system in the past few years (Mereghetti et al. 2009, 2011, 2013, 2016). Mereghetti et al. (2009) detected an eclipse in the X-ray light curve with a period coincident with the
spectroscopic period. This allowed them to derive the inclination of the system and a much more precise measurement of the masses in the system and found $M_{\text{sdO}} = 1.50 \pm 0.05$, $M_{\text{CC}} = 1.28 \pm 0.05$, where $M_{\text{CC}}$ is the mass of the compact companion. They also use the eclipse duration to measure the size of the X-ray emitting region to be $\approx 10^4$ km, which is more that two orders of magnitude larger than the blackbody radius they derive from the X-ray spectrum. Just as in previous studies, the authors used wind-capture accretion rates and compared them to the X-ray luminosity to help distinguish between an NS or a WD companion. Mereghetti et al. (2009, 2011, 2013) all favor a WD over an NS companion, but the new angular momentum and magnetic field analysis in Mereghetti et al. (2016) suggests that an NS companion is more likely. Wang & Han (2010) and Liu et al. (2015) performed calculations for this system assuming a C/O WD companion and concluded that it may be an SN Ia progenitor. We did not pursue such an interpretation for two reasons: (1) C/O WDs are not expected to form above 1.05 $M_{\odot}$, Piersanti et al. (2014), and (2) we expect that shell carbon ignitions would transform C/O WDs to O/Ne before reaching $M_{\text{Ch}}$ (see Section 4).

### 2.2. sdO Modeling

Using MESA, we took the 1.5 $M_{\odot}$ measurement of the mass of the subdwarf derived from the combination of the X-ray mass function and the optical mass function by Mereghetti et al. (2009) and constructed a model starting with a 7.15 $M_{\odot}$ zero-age main-sequence (ZAMS) model, and started mass loss on the EAGB just before the second dredge-up, and ended mass loss when the surface helium mass fraction of the model matched the observed value.

When the effective temperature ($T_{\text{eff}}$) of the subdwarf model reaches the observed 47,500 K, the log $g$ measurement, derived radius, and luminosity all agree with the model within the given error bars, as shown in Table 1. We also show this in the $T_{\text{eff}}$–log $g$ diagram of Figure 1.

At the time when the measurements match the model, the carbon core has grown to 0.71 $M_{\odot}$, and the surface is blowing off a wind at $6 \times 10^{-9} M_{\odot}$ yr$^{-1}$, using the wind prescription from Bloecher (1995) and a scaling factor of 0.05. According to the model, the star will fill its RL approximately 65,000 years from now.

### 3. NS Companion

The measured spin-up rate of $\dot{P} = -2.15 \times 10^{-15}$ s s$^{-1}$ given in Mereghetti et al. (2016) is high for a WD, requiring a relatively large accretion rate. At the maximum wind mass loss rate from the donor of $10^{-8} M_{\odot}$ yr$^{-1}$ (Hamann et al. 1981; Mereghetti et al. 2011), the companion would need to capture all the wind that crosses its RL to cause the measured spin up (see Equation (14) in Mereghetti et al. 2016), which is likely an overestimate of the wind-capture rate. Therefore, we consider an NS interpretation of the compact companion to be much more likely.

If the companion is indeed an NS, there are two ways it could have formed: (1) via a core collapse supernova (CCSN) from a star with a ZAMS mass of $\gtrsim 10 M_{\odot}$, or (2) via AIC where the initially more massive star must have formed an O/Ne WD and subsequently accreted enough mass to reach $M_{\text{Ch}}$. For the AIC progenitor scenario, the sdO star must have been RL filling at the moment of AIC and must be less than half RL filling just after the

### Table 1

| Observable | Observed | 1.50 $M_{\odot}$ Model |
|------------|----------|------------------------|
| $T_{\text{eff}}$ (K) | 47,500 ± 2000 | 47,500 |
| log $g$ (cm s$^{-2}$) | 4.25 ± 0.2 | 4.41 |
| Radius ($R_{\odot}$) | 1.45 ± 0.25 | 1.25 |
| log Lum. ($L_{\odot}$) | 3.90 ± 0.15 | 3.85 |
| $X_{\text{H, surf}}$ | 0.78 ± 0.07 | 0.78 |

Figure 1. Dotted gray square represents the error box of the measurements of the $T_{\text{eff}}$ and log $g$ of HD 49798 from Mereghetti et al. (2009), and the dotted red box is from Müller (2009). The curves show the evolution of helium cores of different masses evolving from the bottom of figure and move toward lower $T_{\text{eff}}$ and log $g$ and are cut off as RLOF begins in the upper right of the plot.

Figure 2. Blue line shows the rate of mass transfer via RLOF. The orange line shows the mass loss rate from the donor via winds. The dark red line shows the Eddington-limited mass gain rate of the NS.
AIC to match the observations. Our calculations, based off the geometry of the system and the fact that the ejected mass from the AIC event (via neutrinos) takes with it the specific angular momentum of the WD, find that the change in the RL radius from that mass and angular momentum loss would only be about 4%. We ran models such that the donor was RL filling just before an AIC and is 4% below RL filling just after the AIC, with a 1.55 day orbital period. Since the donor had a deeply convective envelope and was therefore responding adiabatically to mass loss, the sudden shut-off of mass loss caused the star to shrink, but only to 16% below its RL before expanding to refill its RL, whereas we now observe it as about half-RL filling. If, however, the claimed distance of 650 pc is an underestimate, then the radius of the sdO star would need to be significantly larger to match the measured $T_{\text{eff}}$ and luminosity simultaneously. The problems with this scenario is that the $T_{\text{eff}}$, log $g$, and luminosity are already simultaneously matched for the model discussed in Section 3.1, implying that the radius is very near to what we show in Table 1 (Kudritzki & Simon 1978), and this RL-filling progenitor model discussed here never matches the measured $T_{\text{eff}}$ and log $g$.

Additionally, although small eccentricities are expected for most post-AIC systems, this applies to systems with orbital periods in the range from 10 to 50 days (Tauris 2015), whereas systems with periods of about a day end up in highly eccentric orbits (Chen et al. 2011). Given the uncertainties in tidal circularization timescales for these unusual binaries, however, we cannot say if the absence of an eccentricity provides any constraint on the origin of the compact object (Stickland & Lloyd 1994; Mereghetti et al. 2011).

Furthermore, to achieve the measured surface H fraction in this scenario would require the fine tuning of having the AIC occur just as the last bit of the H-rich envelope was being transferred to the WD, whereas a CE removing only the H-rich envelope and leaving just a little bit of surface H is a much more likely explanation. Therefore, if the companion is an NS, it was most likely formed via CCSN and not AIC.

### 3.1. MESA Modeling of Binary

We use MESA’s binary module to evolve the model in a 1.55 day orbit with a 1.28 $M_{\odot}$ point mass. In our calculations, we assume that the system wind takes with it the specific angular momentum of the companion. The high system wind rates during the Roche lobe overflow (RLOF) phase will be optically thick, assuming spherical symmetry, and reprocess any high-temperature accretion luminosity. If, however, our system-wind angular momentum assumption is a significant underestimate, then the high mass transfer rate experienced when the subdwarf begins RLOF could lead to a merger. We briefly explore the possible outcomes of a merger between the He star and a WD or NS companion in Section 5.

At RLOF the mass transfer rate through L1 quickly grows to $\approx 2 \times 10^{-5} M_{\odot} \text{ yr}^{-1}$, almost all of which is lost from the system due to the Eddington-limited accretion rate of the NS of $6 \times 10^{-8} M_{\odot} \text{ yr}^{-1}$ (Figure 2), meaning that the NS only gains $7.4 \times 10^{-3} M_{\odot}$ during this phase, which spins up the NS to a 33 ms spin period. The system loses mass at such a high rate during RLOF that the wind becomes optically thick for $\approx 10^4$ years. We compute the radius at which the optical depth of the wind reaches unity assuming a spherically symmetric wind, a wind speed of the escape velocity of the companion’s RL, and electron scattering opacity, then use that radius and Eddington luminosity of the NS to compute the $T_{\text{eff}}$ that will be observed during the RLOF stage. As shown in Figure 3, the observed $T_{\text{eff}}$ from the wind decreases to $\approx 2.6 \times 10^4$ K at the highest mass loss rate.

When mass transfer completes and the donor star radius drops below the RL, the mass of the donor is 0.91 $M_{\odot}$ and the orbital period is 2.7 days. At that orbital period, the inspiral time is much longer than the Hubble time, so the fate of this system is to be an intermediate-mass binary pulsar (IMBP) with the 0.91 $M_{\odot}$ C/O WD made from the He star.

### 3.2. Possible ULX Source

Ultraluminous X-rays (ULX) sources are powered by accreting NSs or stellar mass black holes at rates of $\approx 10^{-5} M_{\odot} \text{ yr}^{-1}$ (King et al. 2017). Recent detections of persistent pulsations (see Walton et al. 2017 for a summary) from many of these systems have proven that they often harbor an NS, implying that the accretion rate is $\gtrsim 10^2$ higher than the Eddington accretion rate. The binary evolution just described is a remarkable match for these ULX systems, as it stably provides accretion rates well above $10^{-6} M_{\odot} \text{ yr}^{-1}$ for a non-negligible amount of time ($\approx 80,000$ years) with an orbital period of 1.5 days. To explore the outcome of this type of ULX system, we ran an NS case where we set the maximum accretion rate of the NS to $M_{\text{max}} = 10^{-6} M_{\odot} \text{ yr}^{-1}$. This does not qualitatively change the fate of the system (final donor star mass and orbital period after end of mass transfer are roughly the same) but the NS would reach an even more rapid rotation rate, up to 3 ms (rather than 33 ms), due to the additional accreted material. This is a reasonable scenario for this accretion rate, as the estimated maximum magnetic field strength of $B_0 \lesssim 8.9 \times 10^9$ G (Mereghetti et al. 2016) would not allow for a magnetosphere to form outside the NS.

### 4. WD Companion

If we model the compact companion as a massive WD instead of an NS, the evolution of the He star is identical up until the start of RLOF, and extremely similar afterwards due to the mostly negligible difference in mass retention rates between the given scenarios. The maximum accretion rate of WDs is a few orders of magnitude higher than that for an NS, so a larger fraction of the mass donated by the He star remains in the system, but still more than half the mass is ejected (see Figure 4), taking with it the specific orbital angular momentum of the WD, as in Brooks et al. (2016), see also Wang & Han
The Astrophysical Journal, 847:78 (5pp), 2017 September 20

Brooks, Kupfer, & Bildsten

Merger Scenarios at RLOF

For the simulations shown in Section 3.1, the system mass loss reaches $2 \times 10^{-5} M_\odot \text{ yr}^{-1}$. Since we assume that the system wind takes with it the specific angular momentum of the compact companion, the mass transfer is stable and leads to an overall increase in the orbital period and the binary separation. If, however, this is an underestimate of specific angular momentum of the system wind, the large system mass loss rates, thus the large angular momentum loss rates could lead to a merger.

As mass transfer rates rise due to helium shell burning in the donor, causing the star to rapidly expand into its RL, a large angular momentum loss rate will cause the size of the RL to shrink, increasing the mass loss rate, and will cause even faster angular momentum loss, resulting in runaway mass transfer. The helium from the donor would form a CE, leading to a merger between the compact companion and the $0.71 M_\odot$ C/O core of the donor.

If the compact companion is an NS, then we can use the results from Metzger (2012) to predict the general outcome of such a merger. We use his model NS_C-O_1, as its parameters are similar to HD 49798. Using the wind rate and velocity from the disk and the total mass of the disrupted C/O core (0.71 $M_\odot$), we can estimate the total kinetic energy deposited by this disk wind. Comparing this to the binding energy of the helium, now in a CE, we find that the energy from the disk wind is certainly large enough to eject all of the helium from the system. Most of the disk mass from the disrupted C/O core is blown off in the disk wind, and only $\approx 0.11 M_\odot$ is deposited on the NS, according to estimates from the NS_C-O_1 model from Metzger (2012). This results in an NS of mass $M \approx 1.39 M_\odot$ with a spin period of $P_{\text{spin}} \approx 2.4$ ms, making this a millisecond pulsar of average NS mass.

If the compact companion is a WD, then there would be a similar lead up to the disruption of the C/O core of the donor, but the remnant would last much longer. The disrupted C/O sitting on top of the 1.28 $M_\odot$ O/Ne core would go through a viscous phase and a carbon burning flame as outlined in Schwab et al. (2016), but since the WD would be primarily O/Ne, the flame would quench once it reached the O/Ne core, preventing the lifting of degeneracy of the core. After the C/O burns to O/Ne and becomes part of the degenerate core, the core mass grows above $M_{\text{Ch}}$ and electron captures start to relieve pressure in the center (before reaching conditions for neon burning, see Schwab et al. 2016), leading to an AIC.

6. Conclusions

We have shown that the observations of the sdO star HD 49798 are well fit by a star born with a 7.15 $M_\odot$ ZAMS mass that enters into a CE just before the second dredge-up on the early AGB to become a 1.50 $M_\odot$ He star with a $10^{-2} M_\odot$ H-rich envelope. Furthermore, the observations of the compact companion’s X-ray pulsations suggest that an NS interpretation

Figure 4. Mass transfer rate of a 1.28 $M_\odot$ O/Ne WD in a 1.55 day orbital period binary system with a 1.5 $M_\odot$ He star shown in solid black, which is punctuated by brief mass loss episodes caused by carbon flashes in the helium burning ashes. The solid tracks are the rate at which the WD is gaining mass; the dotted tracks are the rate at which the He star is losing mass. The difference between the dotted and solid track represents the mass that is lost from the system. The stable helium burning boundaries are shown by the dashed red lines from Brooks et al. (2016).
is more likely, but that a WD interpretation cannot be ruled out. We used MESA to simulate the evolution of this system, and predict that, for either an NS or WD companion, the fate of this system is for it to become a wide IMBP with a high mass ($\approx 0.9 M_\odot$) WD and a relatively rapidly spinning NS. This result assumes that the system wind takes with it the specific angular momentum of the compact companion. If, however, the system wind extracts extra angular momentum, then the high mass transfer rates ($\approx 10^{-5} M_\odot$ yr$^{-1}$) can lead to mergers (see Section 5). In the event of a merger, whether the companion is a WD or NS, the predicted fate would be for it to become a solitary NS, which would be an MSP in the case of an NS companion. In the case of a WD companion going into a merger, the resulting spin period after an AIC inside of an extended helium envelope is uncertain.

If the companion is an NS, then we have shown that during accretion, the system may have properties consistent with an ULX. So far only two ULX systems have a confirmed companion. P13 has a confirmed blue supergiant donor of spectral type B9Ia (Motch et al. 2014). The accretor in P13 shows a $0.42$ s slowly spinning up period that demonstrates that the accretor in P13 is an NS (Fürst et al. 2016; Israel et al. 2017). The second known system, M101 ULX-1, has a Wolf–Rayet star donor in an 8.2 day orbit. The accretor is most likely a stellar mass black hole (Liu et al. 2013). Because of the lack of confirmed donor stars in ULX an sdO donor cannot be excluded in other ULXs. Therefore, we conclude that HD 49798 is a plausible progenitor binary to a ULX.

We thank Jim Fuller, Sterl Phinney, and Josiah Schwab for their helpful conversations. This research is funded by the Gordon and Betty Moore Foundation through Grant GBMF5076, and was also supported by the National Science Foundation under grant PHY 11-25915. We acknowledge stimulating workshops at Sky House where these ideas germinated.
