ABSTRACT

We have analyzed the full set of SOHO/MDI f- and p-mode oscillation frequencies from 1996 to date in a search for evidence of solar radius evolution during the rising phase of the current activity cycle. Like Antia et al. (2000), we find that a significant fraction of the f-mode frequency changes scale with frequency; and that if these are interpreted in terms of a radius change, it implies a shrinking sun. Our inferred rate of shrinkage is about 1.5 km/y, which is somewhat smaller than found by Antia et al. We argue that this rate does not refer to the surface, but rather to a layer extending roughly from 4 to 8 Mm beneath the visible surface. The rate of shrinking may be accounted for by an increasing radial component of the rms random magnetic field at a rate that depends on its radial distribution. If it were uniform, the required field would be $\sim 7$ kG. However, if it were inwardly increasing, then a 1 kG field at 8 Mm would suffice.

To assess contribution to the solar radius change arising above 4Mm, we analyzed the p-mode data. The evolution of the p-mode frequencies may be explained by a magnetic field growing with activity. Our finding here is very similar to that of Goldreich et al. (1991). If the change were isotropic, then a 0.2 kG increase, from activity minimum to maximum, is required at the photosphere, which would grow to about 1 kG at 1 Mm. If only the radial component of the field were to increase, then the requirement for the photospheric field increase is reduced to a modest 60-90 G. A relative decrease in temperature of the order of $10^{-3}$ in the sub-photospheric layers, or an equivalent decrease in the turbulent energy, would have a similar effect to the required inward growth of magnetic field change.

The implications of the near-surface magnetic field changes depend on the anisotropy of the random magnetic field. If the field change is predominantly radial, then we infer an additional shrinking at a rate between 1.1-1.3 km/y at the photosphere. If on the other hand the increase is isotropic, we find a competing expansion at a rate of 2.3 km/y. In any case, variations in the sun’s radius in the activity cycle are at the level of $10^{-5}$ or less, hence have a negligible contribution to the irradiance variations.

Subject headings: Sun: radius — Sun: activity — Sun: oscillations — Sun: interior
1. Introduction

Measuring the sun’s radius, and its variability, are significant, long-standing problems, especially in the context of understanding the cause of solar irradiance variations. Recently, it has been pointed out that helioseismology can provide a useful measure of the solar radius. Schou et al. (1997) and Antia (1998) showed that f-modes frequencies are good probes of the radius, and they inferred a value of the solar radius which is about 300 km smaller than the one adopted in solar models at that time. The model values were based on a direct measurement of the sun’s photospheric radius. The smaller radius has been confirmed by Brown and Christensen-Dalsgaard (1998) from many years of transit measurements using the Solar Diameter Monitor. The connection between the “true” solar radius and that inferred from f-modes is explained in Section 3.1.

Following the suggestion of Schou et al. (1997), Dziembowski et al. (1998, 2000) used f-mode data from the MDI/SOHO instrument to determine the evolution of the seismic solar radius through the rising phase of the present activity cycle. They reported statistically significant variations that showed no apparent correlation with activity measures. On the other hand, with GONG f-mode frequencies (ranging between 1.015 mHz to 1.425 mHz, or equivalently ℓ from 100 to 200), covering the rising phase of activity to the beginning of 1999, Antia et al. (2000) found a net decrease of about 5 km in the solar radius. They attributed the difference with Dziembowski et al. (1998) to the latter’s use of higher degree modes (up to ℓ=300). They pointed out the latter ℓ-modes are more likely to be effected by factors other than an evolving radius.

In the present work, we use oscillation data from SOHO/MDI covering 1996.3-2000.5. We first use f-mode data in an effort to infer a signal of radius change. We then modify our earlier analyzes to consider other sources of the variations. Our analysis is preceded by an explanation of the meaning of the “seismic” radius inferred from f-modes. We then compare our results to those of Antia et al., and interpret the inferred rates in terms of magnetic field and temperature changes.

Our interpretation of p-mode frequency changes is predicated on the work of Goldreich et al. (1991) who analyzed BBSO measurements from the rise of the previous cycle (cycle 22). We use our inference on the behavior of the sub-photospheric layers to constrain radius changes arising there.

2. Frequency data from SOHO/MDI

In the present study, we use 19 MDI data sets containing centroid frequencies determined from measurements made between May 1, 1996 and June 21, 2000, with a break between June 16 and October 22, 1998, when there was no contact with SOHO. The sets are typically 72-days long, except those immediately before and after the break, which are shorter. The centroid frequencies, νℓ,n, were determined by the method described by Schou (1999).

The sets contain between 112 and 203 f-mode frequencies, with earlier sets having more data. The maximum ℓ-value is 300 and the minima range from 89 to 137. The number of p-mode frequencies range from 1589 to 1906. Again, the earlier sets are mode abundant. The p-modes range between ℓ=0 and 200. The differences in mode composition are not important in the case of p-modes. The number of overlapping modes is large enough for a detailed study of frequency changes. In the case of f-modes, the difference in the ℓ-range may be important, and therefore in our study of the solar radius changes, we used only modes with ℓ ≥ 137.

3. Inferences from f-mode frequency changes

3.1. Helioseismic radius

All helioseismic determinations of the solar radius to date have relied on the following asymptotic relation for f-modes frequencies,

\[
\frac{\Delta \nu}{\nu} = -3 \frac{\Delta R}{2R}.
\]  

(1)

Antia et al. (2000) pointed out that using this relation for modes with ℓ extending up to 300, as Dziembowski et al. (1998) did, is not justified because of significant departures from \( \nu \propto R^{-1.5} \) are present in higher ℓ’s. The departure increases with ℓ, which as Brown (1984) first suggested could be accounted for as an effect of turbulence in the upper convective zone. Detailed models of this effect have been developed by Murawski & Roberts (1993a, 1993b). (For the most recent work on the subject see Medrek & Murawski 2000). However, surface magnetic fields may also have significant effects on f-mode frequencies (Evans & Roberts, 1990; Jain & Roberts). With these
two sources of perturbation to f-mode frequencies, we must contemplate solar cycle changes beyond that of a simple radius change. The relative contribution of the near-surface changes are expected to increase with ℓ, because such changes should be inversely proportional to mode inertia, \( I_\ell \), which sharply decreases with ℓ.

There is another problem in applying Eq.(1) in a search for the radius variations correlated with activity. This problem follows from the fact that the induced modifications are quite non-uniform, and each f-mode has it own radius, \( R_\ell \), which is given by

\[
R_\ell = \left( \frac{1}{T_\ell} \int r^{-3} dI_r \right)^{-1/3}.
\]

With this definition, we get from the variational principle for oscillation frequencies (see Appendix)

\[
\nu = \frac{1}{2\pi} \sqrt{\frac{GM}{R^3_\ell}}, \tag{3}
\]

where \( L = \sqrt{\ell(\ell + 1)} \). This is a very accurate expression. The relative departures from equality range from \( 2 \times 10^{-4} \) at \( \ell = 100 \) to \( 8 \times 10^{-5} \) at \( \ell = 300 \). In a linear approximation in terms of \( (R - R_\ell) \), this is the same as the formula obtained by Gough (1993).

For high degree modes, the f-mode radii are close to the solar radius. The values of \( R_\ell/R \) range from 0.9883 at \( \ell = 100 \) to 0.9946 at \( \ell = 300 \). While we have \( R_\ell \approx R \), a corresponding approximation for \( \Delta R_\ell \) is quite problematic. When the f-mode frequencies were used to refine the value of the radius for modeling the sun, we could expect an approximate, homologous relation, \( R_\ell \propto R \). But such a relation cannot be expected in the case of the activity induced changes, which we believe to be confined to the outermost part of the sun. If the data show that \( \Delta \nu \) which we believe to be confined to the outermost part is expected in the case of the activity induced changes, then the simplest interpretation, as Antia et al. (2000) found, is that, indeed we have \( \Delta \nu \). Thus, we have no information about the evolution of the photospheric radius of the sun.

3.2. Formal determination of the rate of shrinking from f-modes

To account for the effect of the near-surface changes on f-mode frequencies and possible differential changes, we modified Eq.(1) into

\[
\Delta \nu_\ell = -\frac{3}{2} \frac{\Delta R_\ell}{R} \nu_\ell + \frac{\Delta \gamma_f}{I_\ell}, \tag{4}
\]

where \( \Delta R_\ell \) denotes the radius change inferred from a particular set of f-modes. For the calculation of \( I_\ell \), we adopted the following normalization of the eigenfunctions

\[
(\xi_r)_{pm} = \frac{2 \times 10^4}{\sqrt{\rho R^5}} \nu^m_\ell, \tag{5}
\]

where \( \xi_r \) denotes radial displacement of the fluid element. With such a normalization, the values of \( I_\ell(\nu) \) are of the order of unity for p-modes in the 2–4 mHz range. For the f-modes, the \( I_\ell \) values are significantly larger (see Table 1).

We determined \( \Delta R_\ell \) and \( \gamma_f \) by a least-squares fitting. In Fig. 1, we show values of \( \Delta \nu_\ell \) for selected data sets. The first two sets were obtained at solar minimum. The 1999.4 set was taken near the middle of the phase of rising activity, and the last is at the current maximum. Here, \( \Delta \) denotes the difference between the solar data and the reference model. The reference solar model is that of Christensen-Dalsgaard et al. (1996). It has the same radius used by Dziembowski et al. (1998). That is, the model uses the “old”, too large value of the solar radius (not that of Brown and Christensen-Dalsgaard 1998), and this is why the frequency differences are rather large. A small difference in the reference model radius is inconsequential for the inferred temporal changes.

We assumed that \( \Delta \gamma_f \) is \( \nu \)-independent, and as we see in Fig. 1, the solid line is a good fit to the data. The \( \chi^2 \)'s vary from 1.2 (2000.4 set) to 1.84 (1996.4), except for the significantly worse fit (\( \chi^2 = 3.55 \)) found for the 1998.9 set, which was the first one taken after the recovery of SOHO. We also tried fitting \( \gamma_f \) as a low-order polynomial depending on frequency, but this did not improve the fit.

We see the departure from the linear relationship implied by the the radius adjustment sharply increases with \( \nu \). Antia et al. (2000) considered only modes with \( \nu < 1.44 \) mHz, and it seems that the departure from a straight line is still small. However, this is somewhat misleading because we used a model
with much too large a radius. As we shall see in Table 1, at the level of changes of a few nanohertz (i.e. radius changes of a few km), the difference is quite significant. We emphasize that high $\ell$-modes are important because with increasing $\ell$, $R_\ell$ approaches the solar radius. For such modes, including $\gamma_f$ is essential, which implies that we have to rely on Eq.(4) rather than Eq.(1). With Eq.(1), we get a much poorer fit ($\chi^2 = 4.4 - 16.5$) and the correction to the solar radius is larger by some 20 km. This illustrates the trade-off – increasing $\ell$ moves us closer to the surface, but such high $\ell$’s are more strongly contaminated.

In Fig. 2, we show the variations of the solar radius and $\gamma_f$ inferred from f-modes from the truncated data sets. The rise of the current activity cycle began in 1997.4 which was marked by a sharp rise of the seismic activity indicators (Dziembowski et al. 1998). A corresponding sharp rise of p-mode frequencies beginning at this time may be seen in Fig. 3 here. That is why we choose 1997.4 to begin our linear fits. We have no explanation, as yet, for the relatively large fluctuations in $\Delta R_f$ which appear to have a one-year period. For comparison, we also show the result obtained when the $\gamma_f$-term is ignored. There is a difference, but not as large as one might anticipate by looking at Fig.1. The rate of radius decrease is only insignificantly higher than in our standard version, and the error is larger.

In detail, we found from our linear fit, with the $\gamma_f$,

$$\frac{dR}{dt} = (-1.51 \pm 0.31) \text{ km/y}, \quad (6)$$

and without the $\gamma_f$-term,

$$\frac{dR}{dt} = (-1.82 \pm 0.64) \text{ km/y}.$$  

The values are similar to those found by Antia et al. (2000). To make a closer comparison, we truncated

Table 1: Contributions to f-mode frequency shifts during the rising phase of cycle 23

| $\ell$ | $\nu_\ell$[mHz] | $I_\ell$ | $\Delta \nu_R$[µHz] | $\Delta \nu_\gamma$[µHz] |
|-------|----------------|---------|-------------------|-------------------|
| 100   | 1.02           | 381     | 0.010             | 0.0012            |
| 130   | 1.15           | 165     | 0.011             | 0.003             |
| 200   | 1.43           | 39.     | 0.014             | 0.012             |
| 300   | 1.74           | 9.4     | 0.017             | 0.050             |

Fig. 1.— Differences between measured and calculated f-mode frequencies. The error bars show estimated standard deviations of measured values. The dates correspond to the center of the individual 72-day long measurement periods. The solar model was calculated assuming $R_\odot = 695.991$ Mm. The solid line represents the fit to Eq. (4). The dashed straight line represents the part attributed to the difference between the solar radius and that adopted in the model.

Fig. 2.— Upper panel: Variation of solar radius between 1996.4 and 2000.4 inferred from f-mode frequencies with and without the $\gamma_f$-term. Two straight lines represent linear fits to the data starting from 1997.4 when the rise of cycle 23 began. Lower panel: Corresponding variation of $\gamma_f$, which describes remaining near-surface contribution to f-mode frequency variations.
our data sets at $\ell = 200$, and then we found

$$\frac{dR}{dt} = (-1.80 \pm 0.38) \text{ km/yr}.$$  

Having in mind that we still miss modes between $\ell = 100$ and 137, it is fair to say that there is no disagreement between our findings and theirs, implying that at a depth of from 6 to 10 Mm the sun shrank by some 4 to 6 km during the rising phase of this activity cycle.

How reliable is this finding? The main concern is the role of the near-surface perturbation and the cross-talk between the two terms on the right hand side of Eq.(4). In the lower panel of Fig. 2, we show the $\gamma$’s. The linear fit for $\gamma$, which is visibly poorer, yields

$$\frac{d\gamma}{dt} = (0.180 \pm 0.051) \mu\text{Hz/yr}. \quad (7)$$

The relative contribution of the two terms to overall $f$-mode frequency variations depends on $\ell$. In Table 1, we compare these two contributions, denoted by $\Delta \nu_R$ and $\Delta \nu_\gamma$ for selected $\ell$-values. The increasing role of $\Delta \nu_\gamma$ is a consequence of decreasing mode inertia. It should be noted that $\Delta \nu_\gamma$ yields an appreciable contribution to $\Delta \nu$ even for modes with $\ell \leq 200$. Caution is necessary, but we will proceed further assuming that the effect is indeed real.

### 3.3. Accounting for the rate of shrinkage

Even as small as it seems, a shrinking of the sun’s radius during the rising phase of activity is not easy to explain. To investigate, we write the Lagrangian change of the local radius in the form

$$\Delta r(r_0) = r - r_0 = - \int_{r_0}^{r} \frac{\Delta \rho}{\rho} \left( \frac{x}{r_0} \right)^2 dx, \quad (8)$$

where $r_b$ is the radius at the bottom of the layer perturbed by activity, and $r_0$ is the radius at a specified fractional mass, $M_r/M$, at activity minimum and $\Delta \rho$ denotes the horizontally averaged change of density. We obtain a more revealing form of Eq.(8) by expressing $\Delta \rho$ in terms of the averaged entropy and magnetic field changes.

For the horizontally averaged gas pressure in the presence of a random magnetic field we have, after Goldreich et al. (1991),

$$\Delta P_g = -\Delta (\beta P_m), \quad (9)$$

where

$$P_m = \frac{B^2_h + B^2_e}{8\pi}$$

is magnetic pressure and

$$\beta = \frac{B^2_h - B^2_e}{8\pi P_m}$$

is a measure of the statistical anisotropy of the field.

With the use of thermodynamical relations, we determine

$$\Delta r = \int_{r_0}^{r} \left[ \frac{1}{T_1} \frac{\Delta (\beta P_m)}{P_g} + (-\rho_T)\frac{\Delta S}{c_p} \right] \left( \frac{x}{r_0} \right)^2 dx, \quad (10)$$

where $\rho_T$ denotes the logarithmic derivative of density at constant pressure. The remaining thermodynamical quantities have their standard meanings. At the relevant depths, the gas is nearly ideal. Thus, we may use $\rho_T = -1$, $1/T_1 = 0.6$, and find

$$\frac{\Delta S}{c_p} = \frac{\Delta T}{T} - 0.4 \frac{\Delta P_g}{P_g}.$$

The irradiance from an active sun is higher than average. If the same is true about luminosity then we should have $\Delta S < 0$. Hence, a negative contribution to $\Delta r$. However, this must be very small. If $\Delta S$ refers to the whole convective zone then a $10^{-3}$ luminosity increase translates to an annual decrease in $\Delta S/c_p$ of $10^{-7}$. Another possibility is an increase in the superadiabatic gradient, $\nabla_{\text{con}} - \nabla_{\text{ad}}$, but this seems unlikely too. The annual decrease of $\Delta R_f = 1.5$ km refers to the layer of $r/R = 0.988 - 0.995$. Thus, $\Delta R_f$ must arise mostly beneath $r = R_{137} = 0.988 R$. At this depth, according to a mixing-length model, $\nabla_{\text{con}} - \nabla_{\text{ad}} \approx 2 \times 10^{-4}$, which rapidly decreases going inward. We would need an order of magnitude increase in the superadiabatic gradient to account for our rate of shrinking.

A more acceptable explanation would be a variation in the magnetic field. The consequences of a magnetic field increase depend on $\beta$. For a purely radial field ($\beta = -1$), the increase implies contraction. For an isotropic field ($\beta = 1/3$) the increase implies expansion. The field geometry implying the minimum increase to account for the rate of the shrinking corresponds to $\beta = -1$. Then, we have $\Delta <B>_{\text{rms}} = \sqrt{\Delta (B^2)}$, and assuming a constant rate across the lower convective zone, we infer

$$\frac{d<B>_{\text{rms}}}{dt} \approx 7.2 \text{kG/yr}.$$
The value at \( R_{137} \) may be reduced, for instance, to 1 kG/y if one allows an exponential increase of the rate to about 43 kG/y at the base of the convection zone.

Thus, what we have inferred from the f-mode frequency change is a non-trivial constraint on the internal magnetic field change. Let us note that if the field increase were predominantly isotropic, we would see an expansion rather than a contraction. The field increase inferred from the residual (after removing the near surface contribution) part of the p-mode frequency change was about 60 kG at 25-100 Mm (Dziembowski et al., 2000). This high value could be consistent with the shrinking rate only if \( \beta \) is close to zero, that is if the field is essentially force-free, which is not a likely possibility. Thus, we are now skeptical about the reality of that large field change we reported earlier.

Our inference regarding the solar radius change is limited by the lack of accurate information about what happened in the outer 4 Mm of the solar interior. This is the region where we may expect the largest activity induced variations for two reasons. First, the rapid decline of gas pressure and second, the thermal structure of this layer is more susceptible to changes in the efficiency of the convective energy transport induced by the field changes. The f-mode data we have at hand provide some information about changes in this layer through the \( \gamma_f \). Similar, but much more accurate information is available in the p-mode data, which we now consider.

4. Inference from p-mode frequency changes

Fig. 3.— Variation of the mean value of \( \gamma \) with two versions of its polynomial dependence inferred from p-mode frequencies. As in the case of f-modes shown in Fig. 2, the linear fit corresponds to the data starting from 1997.4 when the rise of cycle 23 began. The error bars would be within the symbols.

4.1. The near-surface source of the p-mode frequency changes

The p-mode spectrum of MDI frequency data is about 13 times richer than that for f-modes. Unfortunately, p-modes are not directly useful for determining changes in the solar radius. The simple relation, \( \nu \propto R^{-1.5} \) would be valid for p-modes only if the changes were homologous throughout the whole sun. This is far from the truth for the changes we are considering here. However, from p-modes one may make a much more precise determination, than from f-modes, of the near-surface perturbation. For p-modes, we call it \( \Delta \gamma_p \), and it describes frequency changes caused by a variable perturbation localized near the surface. In the present application, however, taking into account the \( \nu \) dependence is required for an accurate fit. We express the dependence in the form of a Legendre polynomial series with argument

\[
\Delta \nu_{\ell,n} = \frac{1}{I_{\ell,n}} \sum_{j=0}^{J} \Delta \gamma_{p,j} \cdot P_j(s).
\]

(11)

Here \( \Delta \) is with respect to the 1996.4 data set. The number \( J \) was increased until \( \gamma_{p,0} \) stabilized within the errors and \( \chi^2 \) stabilized. This occurred for \( J = 2 \). In Fig. 3, we plot \( \Delta \gamma_{p,0} \) for \( J = 0 \) and 2. Variations of \( \gamma_p \) are indeed much more accurately determined than those of \( \gamma_f \). For \( J = 2 \), we find the rate

\[
\frac{d \gamma_{p,0}}{dt} = (0.149 \pm 0.008) \ \mu \text{Hz/y}. \quad (12)
\]

The dependence of \( \gamma(\nu) \) yields an important constraint on the localization of the source of solar cycle variations in p-mode frequencies.

Following Goldreich et al. (1991), we link the frequency change to the change of the mean squared magnetic field and a Lagrangian change of a single thermodynamic parameter. For the latter, we prefer to use temperature rather than entropy which was used by Goldreich et al. From Eqs. (14) and (15) of Goldreich et al., we get the following expression for the change of \( \gamma_p \):

\[
\Delta \gamma_p = \frac{1}{8\pi^2 \nu} \int d^3 \mathbf{x} |\text{div} \mathbf{\xi}|^2 \left\{ P\Gamma_1(1 + \Gamma_p) \rho_T \frac{\Delta T}{T} \right\}
\]
Here, we denote by $\Gamma_P$ and $\Gamma_\rho$, the logarithmic derivatives of $\Gamma_1$. The ideal gas equation cannot be used in the layers where most of the contribution to $\Delta \gamma_p$ arises.

Goldreich et al. (1991) explained the p-mode frequency changes during the rising phase of cycle 22 in terms of magnetic field and temperature changes, with former being dominant and causing the frequency increase. They invoked a chromospheric temperature increase to explain the reversal in the increasing trend in $\Delta(\nu)$. We do not see such a trend in our data. Thus, as a first guess we interpret $\Delta \gamma_p$ in terms of magnetic field changes. Later, we will discuss other sources of the p-mode frequency changes.

We considered two values of $\beta$, -1 and 1/3, and the following form for the depth, $D$, dependence of magnetic field increase

$$\Delta <B>_{\text{rms}} = \begin{cases} B_b & \text{if } D \geq D_b \\ B_b + \lambda \left( \frac{D-D_m}{D_b-D_m} \right) & \text{if } D_t < D < D_b \\ \Delta <B>_{\text{rms}} (D_t) & \text{if } D \leq D_t \end{cases}$$

where $D_m = -0.485 \text{Mm}$ denotes $D$ at the temperature minimum, and $B_b$, $D_b$, and $\lambda$ were determined by fitting the three terms in the series given by Eq. (11). For $D_t$ we adopted either $D_m$ or 0.

In Fig. 4 we show two examples of the field’s changing behavior that would be consistent with the observed $\gamma$’s, and compare them with two cases that are clearly inconsistent. One of the two inconsistent cases is a depth independent increase, and the other is an example of the field gradually increasing to about 3 kG at 8Mm. In all four examples, we used $\beta = -1$. We see that indeed the $\gamma_p(\nu)$ provides a strong constraint on the localization of the source of frequency changes, but clearly not a unique answer. For the two fitted cases, the inferred values of $B_b$ are 290 and 250 G. Corresponding values of $B_{\text{ph}} \equiv \Delta <B>_{\text{rms}} (0)$ are 62 and 94 G. An equally good fit was obtained with the choice $\beta = 1/3$. Data on the three models of the magnetic field change fitting $\Delta \gamma_p(\nu)$ data are given in Table 2. The result for $\beta = 1/3$ is not significantly different from that found by Goldreich et al. (1991). To explain the p-mode frequency increase between minimum and maximum, we require an increase of the rms magnetic field growing from 0.2 kG in the photosphere to 0.84 kG at 4.25 Mm. The cor-

![Fig. 4.](image-url)
responding numbers of Goldreich et al. are 0.25 and 1 kG.

In the bottom panel of Fig. 4, we plot the relative temperature changes, which gives the same local contributions to $\Delta \gamma_p$ as the corresponding changes in the magnetic field. We see that the required change of temperature is unacceptably large in the atmospheric layers. However, in sub-photospheric layers we cannot exclude the rms $\Delta T/T$ at the $10^{-3}$ level. Such a temperature decrease would be a significant contributor to the observed frequency increase. Brüggen and Spruit (2000) argue that one expects a lower subsurface temperature from an increasing magnetic field, and that the effect should be searched for by means of helioseismology. A contribution from temperature decrease would lower the requirement for the magnetic field increase in the sub-photospheric layers.

Yet another potential contributor to the frequency increase is a decrease in the turbulent velocity. Roughly, the relative change in the turbulent velocity, $\Delta v_t/v_t = q$, has the same effect as a relative temperature change $\Delta T/T = 0.5qM^2$, where $M$ is the turbulent Mach number. In the sub-photospheric layers, $M$ is in the 0.1–1 range. Thus, the effect may be significant, and we may expect a decrease in $v_t$, with increasing activity, because the magnetic field should inhibit convection.

### 4.2. Shrinking or expanding of the outermost layers

In Table 2, we provide the values of the contribution to the rate of the photospheric radius change due to the magnetic field increase inferred from the $\gamma_p$ changes. We emphasize that the rate does not refer to photosphere but to the mass point corresponding to the unperturbed (solar minimum) photosphere and that the value does not include the part that was inferred from f-mode frequency changes.

The solar photosphere is defined as a surface of specified optical depth $\tau_{ph} = M_{ph}\bar{\kappa}$, where $M_{ph}$ is column-mass depth and $\bar{\kappa}$ is the mean opacity in the atmosphere, or, which is closely related, the place where the local temperature equals the effective temperature. Thus, if we want to assess the rate of movement of the photosphere, we have to take into account a possible change in $\bar{\kappa}$. To keep $\tau_{ph}$ unchanged, an additional radius shift of $-\Delta \bar{\kappa}(dr/d\bar{\kappa})_{ph}$ is needed. Hence, the rate of the photosphere’s change may be assessed as

$$\frac{dR_{ph}}{dt} = \left(\frac{dR}{dt}\right)_{ph} - \left(\frac{dr}{dt} \frac{\bar{\kappa}}{d\bar{\kappa}}\right)_{ph}, \quad (14)$$

An estimate shows that the second term may not be negligible if $(\Delta T/T)_{ph} \sim 10^{-3}$.

The connection between $R_{ph}$ and the solar disk radius, $R_d$, determined from the inflection point in the limb-darkening function was discussed recently by Brown and Christensen-Dalsgaard (1998). They find $R_d - R_{ph} \approx 500$ km. Again a $10^{-3}$ temperature perturbation within the atmosphere may be significant at the level of the radius changes discussed here. Thus, the difference between the solar radius variations inferred by means of seismology and photometry has to be kept in mind when a detailed comparison is made.

The total value of $(dR/dt)_{ph}$ may be estimated as the sum of -1.5 km/s inferred from the f-mode data and one of the values inferred from p-modes data shown in Table 2. These are model dependent. We do not expect that by including the nonmagnetic contributors to $\Delta \gamma_p$, we would infer rates significantly beyond the range of values quoted in this table. We note that the net effect may imply both contraction and expansion. Possible net values of $(dR/dt)_{ph}$ range from -3 to 1 km/y.

Finally, we point out that there is no contradiction between our inferences from f- and p-mode frequency changes. The effect of the field increases needed to account for the $dR/dt$ value have a negligible effect on p-modes frequencies, if the outward decrease of $d < B >_{rms}$ /dt from the bottom of the convective zone is steep enough.

### 5. Conclusions

Results of our analysis of f-mode frequency confirm the evidence, first found by Antia and Basu (2000), for a contraction of the sun’s outer layers during the rising phase of the magnetic activity. The rate we determine is 1.5 km/y and is only somewhat different than found by our predecessors. We pointed out, how-
ever, that there may be another interpretation for the observed frequency variation. Further, we stressed that the rate does not refer to the surface radius, but to the layer at 4 – 8 Mm depth below the photosphere. In spite of the fact that the dispersion relation for high-degree f-modes approaches that for the surface gravity waves, the two types of modes are essentially different. While the latter are discontinuity modes which see the same gravity for each horizontal wave number, the f-modes see different effective gravities depending on ℓ.

The rate of shrinking is most easily explained as resulting from the rise of the radial component of the random magnetic field beneath a depth of 8 Mm. There is an integral constraint on the magnetic field which may be the most important finding from the data on f-mode frequency changes. To account for the shrinking rate, we need an increase in the radial component of the random magnetic field with a modest annual rate. An isotropic increase would imply an expansion in the f-mode region. We pointed out that this new constraint is likely to be in conflict with the much larger change of the interior field inferred by Dziembowski et al. (2000) from the inversion of p-mode frequency changes.

The p-mode frequency change may be accounted for in terms of magnetic field changes. Our analysis was based on the formalism of Goldreich et al. (1991), and we found similar implications regarding the required field increase as these authors, who analyzed BBSO data from the previous solar maximum. In particular, the increase must be larger below the photosphere than in the atmosphere, if this is the sole effect causing p-mode frequency changes. We pointed out, however, that a temperature decrease and/or decrease of turbulent velocity in sub-photospheric layers could be significant contributors to the frequency decrease. Depending on the field anisotropy, the changes in the outermost layers may lead to additional shrinking or to net expansion.

Our estimated rates of radius change during the rise of cycle 23 range from -3 to 1 km/y. This differs from the rate of about 5.9±0.7 km/y determined by Emilio et al. (2000) from the direct radius measurements based on SOHO/MDI intensity data. Perhaps the difference may be explained by the difference between dR/dt and our (dR/dt)pb. Both results, however, imply a negligible contribution of the radius change to the solar irradiance variations. Furthermore, the two estimates of the radius change between maximum and minimum activity are by two orders of magnitude less than found by Nöel (1997) from his measurements with the astrolabe of Santiago. He finds the difference between the 1991 (previous maximum) and 1996 radii which is exceeding 700 km. The data from the Solar Diameter Monitor (Brown & Christensen-Dalsgaard, 1998) are inconsistent with such large variations, although there is a hint of possible radius increase during 1987 of some 30–40 km. On the other hand, a theoretical constraint on radius given by Spruit (1994) is even tighter than that from helioseismology. The number he quotes for the maximum to minimum difference is 2 × 10^{-7} R_⊙ = 0.14 km.

We thank an anonymous referee for careful and detailed comments that improved our paper.

SOHO is a project of international cooperation between ESA and NASA. This research was supported by the SOI-MDI NASA contract NAG5-8878 at Stanford University, and partially supported by NASA-NAG5-9730, NASA-NAG5-9543 and NSF-ATM-97-14796 grants to Big Bear and KBN-2-P03D-014-14 to W.A.D.

**APPENDIX**

We assume the Cowling approximation and write the equation for adiabatic oscillation in the following form

\[ \rho \omega^2 \xi = \nabla P' + \rho' \mathbf{e}_r \equiv \mathbf{F} \xi. \]  

(A1)

The notation here is a standard one and does not require explanation. The variational expression for eigenfrequencies is

\[ \omega^2 = \frac{\int d^3 x \xi^* \mathbf{F} \xi}{\int d^3 x \rho |\xi|^2} = \frac{K}{T}. \]  

(A2)

The f-modes are nearly incompressible. Thus, for the approximate \( \xi \) to be used in this expression, we assume

\[ \nabla \cdot \xi = 0. \]  

(A3)

Then for the Eulerian perturbation of density and pressure, we have

\[ P' = g \rho \xi_r \quad \text{and} \quad \rho' = -\frac{d \rho}{d t} \xi_r. \]  

(A4)

We express in a standard way the displacement eigenvector in terms of the spherical harmonics,

\[ \xi = [y(r) \mathbf{e}_r + z(r) \nabla] Y^m_{\ell}. \]  

(A5)
With this expression (A3) becomes
\begin{equation}
\frac{dy}{dr} + 2\frac{y}{r} - L^2 \frac{z}{r} = 0 \tag{A5}
\end{equation}
and the integrals in (A2) become
\begin{equation}
I = \int_0^R (y^2 + L^2 z^2) \rho r^2 \, dr \tag{A6}
\end{equation}
and
\begin{equation}
K = \int_0^R \left[ 2L^2 yz + \left( \frac{d \ln g}{d \ln r} - 2 \right) y^2 \right] \frac{g}{r} \rho r^2 \, dr, \tag{A7}
\end{equation}
where we made use of (A4). We may use
\[\frac{d \ln g}{d \ln r} = -2,\]
because for modes considered here the logarithmic derivative of the local mass, \(M_r\), is less than \(10^{-2}\) in the layers contributing to \(I\) and \(K\), which implies less than a \(10^{-4}\) fractional contribution to frequencies. From the ratio of radial to horizontal component of (A1), we obtain approximately
\[\frac{y}{z} = L^2 \frac{z}{y},\]
and, taking into account the inner boundary condition, \(y = Lz\). Now, we have from (A6)
\begin{equation}
I = 2 \int_0^R y^2 \rho r^2 \, dr \tag{A8}
\end{equation}
and from (A7)
\begin{equation}
K = 2(L - 2) \int_0^R y^2 \frac{g}{r} \rho r^2 \, dr \tag{A9}.\end{equation}
Eqs. (2) and (3) follow immediately from (A2), (A8), and (A9) upon setting \(M_r = M\) and \(\omega = 2\pi \nu\).
