ABSTRACT

Aims. We explore potential mechanisms to produce extremely high Lyα/HeII flux ratios, or to enhance the observed number of Lyα photons per incident ionizing photon, in extended AGN-photoionized nebulae at high-redshift.  

Methods. We compute models to simulate, in the low density regime, photoionization of interstellar gas by the radiation field of a luminous AGN. We explore the impact of ionization parameter, gas metallicity, ionizing spectrum, electron energy distribution, and cloud viewing angle on the relative fluxes of Lyα, HeII and other lines, and on the observed number of Lyα photons per incident ionizing photon. We compare our model results with recent observations of quasar Lyα halos at z  3.5.  

Results. Low ionization parameter, a relatively soft or filtered ionizing spectrum, low gas metallicity, 4-distributed electron energies, or reflection of Lyα photons by neutral hydrogen can all result in significantly enhanced Lyα relative to other lines (  10%), with log Lyα/HeII reaching values of up to 4.6. In the cases of low gas metallicity, reflection by HI, or a hard or filtered ionizing spectrum, the observed number of Lyα photons per incident ionizing photon is itself significantly enhanced above the nominal Case B value of 0.66 due to collisional excitation, reaching values as high as 5.3 in an ‘extreme case’ model which combines several of these effects. We find that at low gas metallicity (e.g. Z/Z⊙  0.1) the production of Lyα photons is predominantly via collisional excitation rather than by recombination. In addition, we find that the collisional excitation of Lyα becomes much more efficient if the ionizing continuum spectrum has been pre-filtered through an optically thin screen of gas closer to the AGN (e.g., by a wide-angle, feedback-driven outflow). We also show that the Lyα and HeII emission line ratios of the z  3.5 quasars studied by Borissova et al. (2016) are consistent with AGN-photoionization of gas with moderate to low metallicity and/or low ionization parameter, without requiring exotic ionization/excitation mechanisms such as strong line-transfer effects. In addition, we present a set of UV-optical diagnostic diagrams to distinguish between photoionization by Pop III stars and photoionization by an AGN.

1. Introduction

The Lyman-alpha (Lyα λ1216) line of neutral hydrogen is an important observable in that it permits the discovery and study of galaxies at high redshift (e.g. Shibuya et al. 2017a), particularly galaxies in a phase of star formation or active galactic nucleus (AGN) activity. This line is one of the intrinsically most luminous in galaxy spectra, but is relatively unstable as a quantitative diagnostic due to its resonant nature, and also due to its susceptibility to extinction by dust or other effects (e.g. Binette et al. 1993). Despite its significant disadvantages, Lyα remains a key source of observational information about the evolution of galaxies and their gaseous environments across cosmic time (e.g. Haiman and Rees 2001).

Although typically less luminous and thus more difficult to observe, the non-resonant recombination line HeII λ1640 offers additional information to that provided by Lyα. Crucially, the ionization potential of He+ is far higher than that of H0 (54.4 vs 13.6 eV) and the production of a significant flux of HeII relative to Lyα requires an ionizing source with a relatively hard ionizing spectrum, or else significant collisional ionization by shocks.

Used together, Lyα and HeII offer potentially powerful diagnostics of the nature of ionizing sources in high-z galaxies, and a toolbox for understanding the physics of gaseous nebulae therein (e.g. Heckman et al. 1991; Villar-Martín et al. 2007; Arrigoni-Battaia et al. 2015a; Feltre, Charlot & Gutkin 2016; Husemann et al. 2018).

One potentially powerful application of the Lyα to HeII flux ratio is in the identification of Population III (Pop III) stars in the high redshift Universe, by searching for HI regions or star forming galaxies with an emission line spectrum indicative of photoionization by an extremely hot thermal source (e.g., Schaerer et al. 2002). However, care is needed to avoid misclassifying AGN as Pop III and vice versa (see e.g. Fosbury et al. 2003; Binette et al. 2003; Villar-Martín, Cerviño & González Delgado 2004; Sobral et al. 2015, 2017; Bowler et al. 2016).

In addition, the Lyα to HeII flux ratio can inform us about the physics in nebulae associated with powerful AGN. For example, transfer effects and dust can strongly affect this line ratio (e.g. van Ojik et al. 1994; Villar-Martín, Binette & Fosbury 1996), and photoionization modelling also suggests that the gas density and metallicity and the presence of young stars may also impact this line ratio in nebulae that are photoionized by an AGN (Villar-Martín et al. 2007).

Building on previous modeling (e.g., Villar-Martín, Binette & Fosbury 1996; Villar-Martín et al. 2007, Arrigoni-Battaia et al. 2015a,b), we present photoionization model calculations appropriate for large-scale Lyα nebulae photoionized by an AGN. In particular, we explore several potential mechanisms to produce ‘extreme’ Lyα and HeII emission line ratios, or an enhance-

2. Defining ‘extreme’ Lyα flux ratios

This study was motivated in part by the recent discovery by Borisova et al. (2016) of Lyα halos around a number of quasars at z ~ 3.5, with Lyα/HeII λ1640 flux ratios that are typically significantly higher than those measured from the spatially integrated spectra of powerful radio galaxies at z > 2 (e.g., Vernet et al. 2001; Villar-Martín et al. 2007).

Following Villar-Martín et al. 2007, we consider Lyα/HeII λ1640 > 15 (1.18 in log) to be an ‘extreme’ ratio. This is above the normal range of values shown by high-z radio galaxies (see also De Breuck et al. 2000; Vernet et al. 2001), and above the range of values produced by ionization-bounded photoionization models that are able to reproduce the UV line ratios of z ~ 2 radio galaxies (see, e.g., Villar-Martín, Tadhunter & Clark 1997, Villar-Martín et al. 2007).

3. Photoionization modeling

In order to examine how various physical conditions and the nature of the ionizing source can affect the emergent emission line spectrum of a photoionized nebula, we have computed a grid of photoionization models using the multi-purpose modeling code MAPPINGS 1e (Binette, Dopita & Tuohy 1985; Ferruit et al. 1997; Binette et al. 2012).

Some regions of parameter space we investigate here have also been explored previously (e.g., Villar-Martín, Binette & Fosbury 1996; Villar-Martín et al. 2007; Arrigoni-Battaia et al. 2015a, b). Here we build on existing work by considering a wider range of parameter space, additional parameters, and previously unexplored combinations of parameters.

Note that 2-photon emission is present in all our models, due to the modeled plasma being in the low-density regime.
3.1. Fixed Parameters

We keep several model parameters fixed throughout this study. For simplicity, we adopt an isochoric, plane-parallel, single-slab geometry. By default, the models are ionization-bounded unless otherwise stated, with computation terminated when the ionization fraction of hydrogen falls below 0.01.

3.2. Gas Density $n_H$

Throughout this paper, we define $n_H$ as the Hydrogen gas number density within our line emission models. Thus, all values of $n_H$ discussed herein are not necessarily directly equivalent to the volume-averaged gas densities which are often preferred when modeling large scale structure (e.g., Rosdahl & Blaizot 2012).

We have adopted 100 cm$^{-3}$ as our default hydrogen number density, because we aim to simulate spatially extended, low density gas rather than compact regions of high density gas closely associated with the central AGN, whose gas clouds typically have $n_H$ > 1000 cm$^{-3}$. To test the impact of lower gas density on the Lyα emission, we have computed additional models using $n_H = 0.1$ cm$^{-3}$ corresponding to the volume-averaged gas density in the outskirts of high-z quasar halos predicted by the numerical simulations of Rosdahl & Blaizot (2012).

3.3. Ionization Parameter $U$

The ionization parameter $U$ is effectively a measure of the ratio of ionizing photons to particles in the model gas cloud, and provides a useful parameterization of the ionization state of the gas. High-$z$ Lyα emitters can be very large ($r > 100$ kpc), and there is a potentially very large range in $U$ between individual objects and between different regions of objects, depending on $r$, $Q$, $n_H$, etc. For example, a cloud of gas in the outer Lyα halo of a luminous quasar might have $\log U \sim -2.5$ (assuming $Q \sim 10^{56}$ s$^{-1}$, $r \sim 100$ kpc, $n_H \sim 10$ cm$^{-3}$). A cloud closer to the quasar for instance might have $\log U \sim -1.5$ (with $r \sim 1$ kpc, $n_H \sim 1000$ cm$^{-3}$). On the other hand, a cloud might have $\log U \sim -4.5$ with $n_H \sim 1$ cm$^{-3}$ at a distance of $r \sim 1$ Mpc from a quasar. Thus, we should consider a suitably large range in $U$. Our model grid contains 100 values of $U$, starting at $\log U = -5$ and ending at $\log U = 0.25$. We increase $U$ by +0.0531 dex (i.e., a factor of 1.13) between each model in the $U$-sequence to obtain a relatively fine sampling of this parameter.

3.4. Ionizing Powerlaw Index

By default, we adopt a power law with the canonical spectral index $\alpha = -1.5$ (e.g., Robinson et al. 1987), where $S_{\nu} \propto \nu^{\alpha+2}$ (see also Telfer et al. 2002). However, it has been suggested that AGN at high redshift (i.e., $z > 2$) have a significantly harder ionizing spectrum (e.g., Francis 1993; Villar-Martín et al. 1997). On the other hand, it is conceivable that some active galaxies at high redshifts may instead have softer ionizing SEDs, due to the presence of a massive starburst which could contribute photons to the ionization of the extended Lyα halo (e.g. Villar-Martín et al. 2007), or perhaps due to partial filtering of the AGN’s ionizing continuum in a circumnuclear screen of gas (e.g., Binette et al., 2003). To test the impact of adopting a harder or softer powerlaw, we have also computed model sequences using $\alpha = -1.0$ or $\alpha = -2.0$.

3.5. Gas Chemical Abundances

We also vary the gas chemical abundances, to examine the impact of metallicity on the emergent emission line spectrum. As the starting point for the chemical abundance sets considered here, we adopt the Solar chemical abundances as determined by Asplund et al. (2006). For non-Solar gas abundances, we scale all metals linearly.

Lyα emitting regions associated with galaxies at high-$z$ have a potentially very large dispersion in gas metallicity, ranging from extremely metal poor gas on the outskirts of a very young galaxy at high redshift, to metal-enriched gas close to the active nucleus of a massive galaxy. Thus, we consider three representative gas metallicities of $Z = 0.01, 0.10,$ and 1.0 times the Solar metallicity ($Z_{\odot}$).

3.6. Electron Energy Distribution and $\kappa$

Among the novel features of MAPPINGS 1e is the ability to use the non-equilibrium, Kappa-distribution (KD) of electron energies instead of the commonly adopted Maxwell-Boltzmann distribution (MBD). The KD of electron energies used in MAPPINGS 1e is a function of electron temperature and the $\kappa$ parameter, where $1.5 < \kappa < \infty$, and is described in Nicholls et al. (2012; see also Vasyliunas 1968). When $\kappa \rightarrow \infty$, the distribution becomes a MBD. Full details of the implementation of KD electron energies in MAPPINGS 1e are given in Binette et al. (2012).

Although the physics underpinning the KD is not yet fully understood (see, e.g., Ferland et al. 2016; Draine & Kreisch 2018), the presence of KD energies in Solar System plasmas is well established (e.g. Vasyliunas 1968; Livadiotis & McComas 2011; Livadiotis 2018). Thus, it is important to consider the possibility that KD electron energies may be present in some extrasolar and extragalactic plasmas.

Indeed, a number of recent studies have shown that many commonly observed nebular emission lines can be significantly affected by adopting the KD, both in HII regions and high-$z$ radio galaxies, and the KD has been proposed as a solution to the long-standing observational temperature discrepancies in planetary nebulae and HII regions (Nicholls et al. 2012, 2013; Binette et al. 2012; Humphrey & Binette 2014).

Values in the range $10^{0} \leq Z \leq 10^{4}$ have been proposed for HII regions and planetary nebulae (e.g. Nicholls et al. 2012; Binette et al. 2012) and AGN (Humphrey & Binette 2014), where a smaller $\kappa$ represents a stronger deviation from the MBD. In this Paper we consider $\kappa = 20$ in place of the MBD distribution in some model sequences.

3.7. Cloud Viewing Angle

As previously shown by Villar-Martín, Binette & Fosbury (1996), neutral hydrogen at the back of the cloud can act as a ‘mirror’ to back-scatter Lyα towards the front of the cloud, enhancing the flux of Lyα as seen by the observer, relative to other lines. To avoid confusion with other geometrical set-ups, we refer to this neutral ‘mirror’ at the rear of the cloud as a ‘back-mirror’.

We consider two viewing angles for the model cloud (slab). By default, we have adopted the ‘side view’, which places the
Fig. 2. Selected sequences in U plotted for Lyα/HeII vs. Lyα/Hβ, Lyα/Hα, Hα/Hβ, or [OIII] λ5007 / Hβ. Each sequence represents a progression in U, for each of the three values of Z. Also shown are sequences in U using κ=20 for Z/Z⊙=0.01 and 1.0 (dotted curves). All models in this figure use power index α=-1.5. The lower two panels show Lyα/HeII vs. U (left) and the ratio of Lyα photons to ionizing photons (ηLyα; right) for the same model sequences. The model loci cover the range of ionization parameter -5<log U<0.25.
observer at an angle of 90° to the direction of travel of the incident ionizing radiation. In addition, we also calculate the ‘front view’, where the observer views the illuminated face of the cloud (see Binette et al. 1993a,b).

In all of our ionization-bounded models, the column density of neutral hydrogen towards the back of the cloud \( N_{\text{HI}} \geq 10^{18} \text{ cm}^{-2} \) is substantially higher than what is required to produce a significant neutral ‘back-mirror’ effect (the minimum required is \( N_{\text{HI}} \geq 10^{14} \text{ cm}^{-2} \)).

This ‘back-mirror’ effect would be much weaker in models in which the illuminated gas is optically thin to ionizing radiation (matter-bounded), such as the filtering screen described in Sect. 3.8 below, or the optically thin photoionization models that Arrigoni Battaia et al. (2015b) favoured in explaining the Ly\( \alpha \) emission from the giant gas halo of the \( z=2.28 \) quasar UM287.

Note that to reflect Ly\( \alpha \) photons from the active nucleus (whether hidden or viewed directly), such neutral ‘back-mirrors’ as considered here are not strictly needed. This is because even a matter-bounded HII slab of reasonable opacity (e.g. Binette, Wilson & Storchi-Bergmann 1996) will have a non-negligible (whether hidden or viewed directly), such neutral ‘back-mirrors’ effect; potentially providing a further enhancement to the flux of Ly\( \alpha \). However, we do not consider this additional effect here.

3.8. Ionization by a filtered SED

We also study the impact of photoionizing gas clouds using an ionizing powerlaw SED that has first been filtered through a screen of gas that does not fully absorb all ionizing photons. A situation where this might occur would be in a galaxy which contains a wind-blown superbubble that is expanding into the extended gaseous halo (e.g. Tenorio-Tagle et al. 1999; Taniguchi et al. 2001). In this case, one would expect the bubble to partially filter the AGN’s ionizing continuum so that gas clouds at radii beyond the bubble would see an altered version of the ionizing SED. Alternatively, the ionizing spectrum of the AGN might be filtered by gas in the host galaxy, before escaping to ionize gas on hundreds of kpc scales, giving essentially the same result.

Several previous studies have addressed this issue (see e.g. Binette, Wilson & Storchi-Bergmann 1996; Binette et al. 2003), and among the main effects are lower fluxes for HeII and other high-ionization lines, and lower electron temperatures, than would have resulted using the original (unfiltered) SED.

Here, we look specifically at the impact of a filtered ionizing SED on Ly\( \alpha \) flux ratios. For this, we have produced a set of four filtered SEDs by computing matter-bounded photoionization models with \( \alpha=-1.5 \), log \( U=-2 \), and \( N_{\text{HI}} = 1.0, 2.5, 5.0 \) or \( 7.0 \times 10^{20} \text{ cm}^{-2} \), giving ionizing continuum escape fractions of \( F_{\text{esc}} = 0.90, 0.74, 0.50 \) and 0.28, respectively. The choice of values for \( U \) and \( N_{\text{HI}} \) are not critical, and can be scaled in lock-step to produce a similar emergent distribution. The metallicity of the screening gas is assumed to be solar. The resulting ionizing SEDs were then used as inputs for new, U-sequence model calculations.

The various filtered SEDs are shown in Fig. 1. The main dips seen in our filtered SEDs are caused by photoelectric absorption of photons by H (13.6 eV) and He\(^+\) (54.4 eV), resulting in a spectrum with a comparatively lower number of He\(^+\) ionizing photons. For comparison, we also show the residual of an \( \alpha=-1.5 \) ionizing SED from an unfiltered model calculation.

When computing models using a filtered SED, we have scaled by \( F_{\text{esc}} \) the range in \( U \) values covered. For instance, when using our \( F_{\text{esc}}=0.28 \) SED, our \( U \)-sequences run from log \( U = -4.55 \) to log \( U = -0.30 \). This introduces a differential shift in the curves that are plotted as a function of \( U \). To facilitate visual comparison between models, we show in Appendix A the same models as a function of \( U = U / F_{\text{esc}} \).

Note that we do not include line emission produced within the filtering screen in the resulting line fluxes from our filtered continuum models. The relative significance of the line flux from the absorbing screen depends strongly on its physical conditions, and can vary from significant when the screen and post-screen gases have similar physical conditions (see the models of Binette, Wilson & Storchi-Bergmann 1996), to negligible as in the case where the filtering screen is obscured (from the observer) by nuclear dust. A full treatment of the emission from such a screen is beyond the scope of this Paper.

3.9. Ionization by Pop III stars

We also include a model sequence to simulate a low-metallicity nebula being photoionized by Pop III (or Pop III-like) stars, with the aim of understanding to what extent their Ly\( \alpha \) flux ratios differ from those of our AGN models.

Taking into account the effect of He\(^+\) opacity, a zero-metallicity star with an effective temperature of 80 000 K would be equivalent to a black-body of 67 200 K in terms of the proportion of He\(^+\)-ionizing photons (see Holden et al. 2001; Schauer 2002; Binette et al. 2003). Thus, we adopt a black-body temperature of 67 200 K in this model sequence.

We also use a gas phase metallicity of \( Z/Z_{\odot} = 0.01 \), to account for some slight pollution with metals, and for consistency with the low-metallicity AGN powerlaw models against which our Pop III models will be compared. For easy comparison with our AGN models, our Pop III models use an ionization-bounded, plane-parallel geometry and \( n_{\text{H}} = 100 \text{ cm}^{-3} \).

It is not our intention to model in detail the expected line spectrum of a Pop III-ionized nebula, but to reach a general overview of the potential for such a nebula to be confused with an AGN-photoionized nebula when only the strongest UV emission lines are available.

We stress that this model sequence may be unrealistic in that true Pop III stars are expected to form from chemically primordial gas, with the associated HII region being similarly devoid of metals. Our model sequence, however, does consider a zero-metallicity Pop III star (or stars), but the gas it photoionizes has already undergone some slight pollution with metals. In a future paper we will present a more detailed modeling of emission line diagnostics for Pop III HII-regions and Pop III galaxies.

4. Results

Here we describe the results from our model grid using diagnostic diagrams, which we show in Figs. 2–7.

4.1. AGN models – line ratios

Our modeling shows that ‘extreme’ ratios of Ly\( \alpha /\text{HeII} \) can be readily produced using AGN photoionization. Within our model grid this flux ratio spans a huge range in values, from log \( \text{Ly} \alpha /\text{HeII} = -1.1 \) to \( -4.6 \), without the need to invoke physically im-
Fig. 3. The impact of the powerlaw index of the ionizing spectrum on \( \log \frac{\text{Ly}\alpha}{\text{HeII}} \), \( \log \frac{\text{Ly} \alpha}{H\beta} \) and \( \eta_{\text{Ly} \alpha} \). The model loci cover the range of ionization parameter \(-5<\log U<0.25\).

Fig. 4. The impact of viewing angle on the observed \( \log \frac{\text{Ly} \alpha}{\text{HeII}} \), \( \log \frac{\text{Ly} \alpha}{H\beta} \) and \( \eta_{\text{Ly} \alpha} \) values. The green curve shows the locus of our sequence in U using \( \frac{Z}{Z_\odot}=0.01 \), \( \alpha=-2.0 \) and the ‘front view’, to illustrate the combined effect of low U, low gas metallicity, a relatively soft ionizing continuum, and a ‘back-mirror’. The model loci cover the range of ionization parameter \(-5<\log U<0.25\).
Fig. 5. The impact of using a filtered ionizing continuum instead of a simple powerlaw on the observed values of \( \text{Ly} \alpha/\text{HeII} \), \( \text{Ly} \alpha/\text{H}\beta \) and \( \eta_{\text{Ly} \alpha} \). U-sequences using a filtered ionizing continuum are labeled with their value of \( F_{\text{esc}} \). U-sequence loci which use our default powerlaw of \( \alpha = -1.5 \) are labeled '1.0' because the input SED is unfiltered. The dot-dashed curve (on the right of the upper panel) shows the locus of our sequence in U that uses \( F_{\text{esc}} = 0.28 \), \( Z/Z_\odot = 0.01 \), \( \alpha = -1.5 \) and the 'front view', to illustrate the combined effect of low U, low gas metallicity, a heavily filtered ionizing continuum, and a 'back-mirror'. For each combination of U and \( Z/Z_\odot \), a lower \( F_{\text{esc}} \) results in lower \( \text{Ly} \alpha/\text{HeII} \) and higher \( \eta_{\text{Ly} \alpha} \). In Fig. A.1 we show an alternate version of this Figure, plotted with U scaled by \( 1/F_{\text{esc}} \) to aid comparison with our other models.

Fig. 6. The impact of gas density on the observed \( \text{Ly} \alpha/\text{HeII} \), \( \text{Ly} \alpha/\text{H}\beta \) and \( \eta_{\text{Ly} \alpha} \) values. The model loci cover the range of ionization parameter \(-5 < \log U < 0.25\).
plausible values for model parameters. Below we describe the impact of individual parameters on the line ratios, giving examples to quantify the impact at specific positions within our parameter space.

We find that Lyα/HeII is extremely high when U is relatively low, regardless of which electron energy distribution and gas metallicity are selected, as can be seen in Fig. 2. For example, at Z/Z⊙ =0.1 and log U = -4 we obtain log Lyα/HeII=1.88. There is essentially no upper limit to the Lyα/HeII flux ratio, with Lyα/HeII → ∞ as U → 0 (log U → -∞).

We also note that most of the model sequences show at their high-U end (log U > α ple, at metallicity are selected, as can be seen in Fig. 2. For example, U = -2 and α = -1.5, moving from Z/Z⊙ =1.0 to Z/Z⊙ =0.1 changes log Lyα/HeII from 1.25 to 1.46 (+0.21 dex); log Lyα/HeII from 1.43 to 1.59 (+0.16 dex); Lyα/Hα from 0.96 to 1.10 (+0.14 dex); Hα/HeII from 0.46 to 0.49 (+0.03 dex).

The impact of using the κ-distribution is complex and varies across the range in parameter space we examine in this work. Generally speaking, using κ=20 results in a minor enhancement of Lyα relative to HeII, Hβ and Hα at high metallicity (Z/Z⊙ ≥1.0), but when metallicity is low (Z/Z⊙ ≤0.1) the Lyα is marginally reduced relative to those lines. For instance, at log U = -2, α = -1.5 and Z/Z⊙ ≥1.0, log Lyα/Hβ changes from 1.43 to 1.46 (+0.03 dex) when adopting κ =20, but at Z/Z⊙ ≥0.1 we find that using κ =20 reduces log Lyα/Hβ from 1.59 to 1.58 (-0.01 dex). In other words, the impact on Lyα of adopting a κ-distribution with κ=20 is marginal to insignificant, at least in the range of parameter space we consider herein. A full analysis of the impact of using the KD in place of the MBD on the emergent spectrum of active galaxies and high-z Lyα emitters will be presented in a future Paper (Morais et al. in prep.).

Fig. 5 shows the impact of using different ionizing spectral indices (α). As expected from previous studies (e.g., Humphrey et al. 2008; Arrigoni et al. 2015b), the Lyα/HeII flux ratio is higher when using a softer ionizing spectrum, because there are relatively fewer photons able to ionize He" (hν >54.4 eV). However, a softer ionizing SED results in a reduction in the flux of Lyα relative to Hβ and Hα, and a reduction in Hα/HeII, because a softer SED results in lower electron temperatures, reducing the importance of collisional excitation effects on these lines. For instance, at log U = -2 and Z/Z⊙, we find that moving from α = -1.0 to α = -2.0 changes log Lyα/HeII from 1.17 to 1.44 (+0.27 dex), log Lyα/Hβ from 1.59 to 1.37 (-0.22 dex), log Lyα/Hα from 1.11 to 0.91 (-0.20 dex), log Hα/HeII from 0.48 (3.04) to 0.45 (2.84), and < T REST > from 14700 K to 9200 K.

In Fig. 4 we show the effect of adopting the ‘front view’ in our adopted geometry. In our models, the observed flux of Lyα (relative to other lines) is nearly twice that of the ‘side view’, with HII in the partially ionized / neutral zone reflecting almost all of the incident Lyα emission, close to the factor 2.0 (0.3 dex) theoretical maximum effect for a uniformly flat ‘back-mirror’ with a covering factor of unity. Interestingly, Fig. 4 also reveals a degeneracy between metallicity and cloud viewing an-
Table 1. Illustrating the impact of low gas metallicity and/or a filtered ionizing SED on the production of Lyα. Columns are as follows: (1) Gas metallicity normalised to the Solar value; (2) log of the ionization parameter U; (3) ionizing SED used (including a black-body SED with $T=45,000$ K); (4) Average electron temperature in the H$^+$ zone; (5) hydrogen neutral fraction; (6) ratio of the column density of ionized hydrogen to the column density of fully-ionized helium; (7) Balmer decrement; (8) Lyα to HeII 1640 flux ratio; (9) $\eta_{Ly\alpha}$, the ratio of Lyα photons emitted to incident ionizing photons. The rows have been sorted using $\eta_{Ly\alpha}$. As discussed in the main text, reducing the gas metallicity raises the electron temperature, leading to increased collisional excitation of Lyα (and of H$\alpha$ relative to H$\beta$), thus increasing $\eta_{Ly\alpha}$. In addition, adopting a filtered ionizing SED (here we show the $F_{esc}=0.28$ case) has the dual effect of reducing the abundance of He$^{++}$ relative to H$^+$ and increasing the collisional excitation of Lyα, with the latter effect resulting in increased $\eta_{Ly\alpha}$.

| $Z/Z_{\odot}$ | log U | SED          | $<T_{He^+}>$ (K) | $H^0/He^0$ | $H^+/He^{++}$ | $H_{\beta}/H^0$ | Lyα/HeII1640 | $\eta_{Ly\alpha}$ |

As shown in Fig. 2 (lower right), the gas metallicity can have a strong effect on $\eta_{Ly\alpha}$, with lower metallicities resulting in higher values of $\eta_{Ly\alpha}$ (see also Table 1). For instance, reducing $Z/Z_{\odot}$ from 1 to 0.01 increases $\eta_{Ly\alpha}$ by a factor of ~2. Interestingly, some of our model loci show a substantial drop in $\eta_{Ly\alpha}$ at higher values of $\log U>2$, particularly in model sequences which use low gas metallicity ($Z/Z_{\odot} \leq 0.1$) and a hard ionizing SED ($a_2$=-1.5; see, e.g., Fig. 3). Interestingly, when the gas metallicity is sufficiently low ($Z/Z_{\odot} = 0.01$), the rate of collisional excitation$^3$ can become the dominant channel for the production of Lyα photons, i.e., at $\eta_{Ly\alpha} \approx 1.4$.

In the low density limit and when the Lyman series is optically thick (Case B), $\eta_{Ly\alpha} \approx \alpha_{esc} f_H |Z_{alpha}| \approx 0.67(T_{He^+}/10^4K)^{0.054}$, where $\alpha_{esc}$ is the total recombination coefficient and $f_H$ is the effective recombination coefficient for Lyα (see e.g., Binette et al. 1993b). In this regime, values of $\eta_{Ly\alpha} \approx 0.7$ indicate a significant contribution to Lyα production due to collisional excitation, while $\eta_{Ly\alpha} \approx 1.4$ indicates that collisional excitation is the dominant channel for Lyα production.

In summary, we find a substantial variation in $\eta_{Ly\alpha}$ between our $n_H=0.1$ and $n_H=100$ cm$^{-3}$ models (Fig. 6).

In addition, we find that using a filtered ionizing spectrum (Fig. 5) results in an increased $\eta_{Ly\alpha}$, with more strongly filtered spectra producing higher values of $\eta_{Ly\alpha}$. This is primarily due to the increased importance of collisional excitation under such conditions. Note that this effect also results in an increased Balmer decrement (see Table 1).

We find no significant difference in $\eta_{Ly\alpha}$ between our $n_H=0.1$ and $n_H=100$ cm$^{-3}$ models (Fig. 6).

$^3$ In the low density limit and when the Lyman series is optically thick (Case B), $\eta_{Ly\alpha} \approx \alpha_{esc} f_H |Z_{alpha}| \approx 0.67(T_{He^+}/10^4K)^{0.054}$, where $\alpha_{esc}$ is the total recombination coefficient and $f_H$ is the effective recombination coefficient for Lyα.

4.3. Degeneracy between AGN and black-body models

Fig. 7 shows a comparison between our Pop III U-sequence and AGN U-sequences with the following parameters: (1) $a_2$=-1.5; (2) $a_2$=-1.5 with the ‘front view’ of a photoionized slab with a ‘back-mirror’; (3) $a_2$=-2.0; (4) photoionization by an $a_2$=-1.5 powerlaw that has been filtered such that $F_{esc}=0.50$. All the models use $Z/Z_{\odot}=0.01$.

Comparing models with identical values of U, we find that the Pop III models give Lyα/HeII ratios that are around one order of magnitude higher than in the powerlaw AGN models. Nonetheless, three of the AGN sequences do show an overlap in Lyα/HeII with the Pop III sequence. The low-U ends of the $a_2$=-2.0 and the $a_2$=-1.5 ‘front view’ sequences reach up above log Lyα/HeII~2.5, while the $F_{esc}=0.50$ filtered continuum model...
overshoots with the full range of Lyα/HeII values in the Pop III model sequence. In other words, it is not possible to distinguish between photoionization by an AGN or by Pop III stars on the basis of the Lyα/HeII ratio alone.4

However, the addition of a second line ratio eases the degeneracy between our model sequences. Of the four diagnostic diagrams shown in Fig. 7, the diagram showing Lyα/HeII vs Lyα/Hβ yields the cleanest separation of models, with the AGN sequences falling below and/or to the right of the Pop III model sequence, because their ionizing SEDs contain a higher proportion of He+ ionizing photons, and/or because the ionized gas has a higher T_e. This diagram also provides a clear diagnostic to distinguish cases of ionization by a relatively soft source (e.g., Pop III stars of an α∼−2.0 powerlaw) from AGN-photoionization by an α∼−1.5 powerlaw with enhanced Lyα emission due to scattering effects (e.g., our ‘front view’ models). Using a softer ionizing SED shifts a model upwards, while scattering-enhanced Lyα shifts a model up and right.

The other three diagnostic diagrams in Fig. 7 show Lyα/HeII vs Lyα/CIV (λ1549, λ1907,1909 and λ3236). There is a relatively clean separation between the Pop III sequence and the power-law AGN models, which run roughly parallel to each other. Only at their very low-U end do the α∼−2.0 and ‘front view’ model sequences cross the locus of Pop III models.

Interestingly, the filtered AGN continuum sequence crosses the Pop III sequence in all three of our Lyα to carbon diagrams, indicating a degeneracy between these two types of model when Lyα/HeII is used together with ratios involving CIV, CIII] and/or CII] (see also Fosbury et al. 2003; Binette et al. 2003).

5. Discussion

5.1. On the extreme Lyα/HeII ratios around z > 3 quasars

Recently, Borissova et al. (2016) discovered ubiquitous, large-scale Lyα emitting halos around 19 quasars at z∼3.5. Interestingly, the authors found extreme Lyα/HeII flux ratios in 11 of the 19 halos, typically with higher Lyα/HeII ratios than in high-redshift radio galaxies.

A number of earlier observational studies have also detected extremely high Lyα/HeII flux ratios in extended Lyα-emitting regions around distant AGN, with proposed explanations including enhanced Lyα flux due to the resonance scattering reflection of Lyα by a large-scale uniform halo of neutral or possibly matter-bound gas (see Sect. 3.7), or recombination emission resulting from photoionization of metal-poor gas by the AGN, (e.g. Villar-Martín et al. 2007; Humphrey et al. 2013a; Arrigoni Battaia 2015b).

Our modeling has confirmed that scattering effects can indeed lead to up to a factor of ∼2 enhancement of Lyα/HeII, under circumstances that may plausibly be present in the Lyα nebulae of some high-z AGN (see also, e.g., Villar-Martín, Binette & Fosbury 1996). However, our models also show that photoionization by an AGN can produce extreme values of Lyα/HeII even without Lyα scattering effects. These include low gas metallicity, a soft or filtered ionizing SED, or a low ionization parameter.

In Fig. 8 we show a selection of relevant photoionization models from our grid, together with the Lyα/HeII flux ratios of Borissova et al. (2016). A horizontal line at log Lyα/HeII = 1.18 delineates the ‘extreme’ and ‘normal’ Lyα/HeII regimes defined in Section 2.

Interestingly, all of the ionization models shown in Fig. 8 lie within the ‘extreme’ regime, although at high U the Z/Z⊙ = 1.0, α∼=1.5 curve comes close to the boundary. Thus, we argue that unless log U ≥ 2.5 and Z/Z⊙ = 1, one should expect the intrinsic (emitted) Lyα/HeII ratios of quasar-photoionized halos to be well within the ‘extreme’ regime. We also suggest that for a quasar-ionized halo to appear well inside the ‘normal’ regime (log Lyα/HeII ≤ 1), its Lyα emission would need to be either strongly absorbed, or else would need to contain a substantial population of matter-bounded clouds that are sufficiently thin for He to be mostly doubly-ionized.

The majority of the quasars in the sample of Borissova et al. (2016) have only lower limits on Lyα/HeII and Lyα/CIV. Unfortunately, these limits are consistent with essentially all of the models we have considered, and thus we cannot place meaningful constraints on properties such as U, Z, α, etc. for the gas halos of these particular quasars.

Only two quasars in the sample of Borissova et al. (2016) have detections of narrow HeII, and both show large vertical offsets of ∼0.3 dex from our AGN powerlaw models. One of these quasars, PKS 1937-101 at z=3.77, shows log Lyα/HeII = 0.92, placing it within the ‘normal’ Lyα/HeII regime in Fig. 8 (red data point). Its position ≥0.2 dex below all of our models (including our Z/Z⊙ = 1.0, α∼=1.0 models) suggests that this quasar halo suffers from strong absorption of Lyα (N_HI ∼ 10^14 cm^-2), is ionized by an unusually hard SED (i.e., α < −1.0), or is composed of matter-bounded clouds rather than the ionization-bounded clouds modeled here.

The other quasar from this sample with a detection of both HeII and CIV is CTS R07.04, at z=3.35 (cyan point in Fig. 8). Its Lyα halo has log Lyα/HeII ∼= 2 and log CIV/HeII ∼= 5, placing it ≥0.4 dex above our powerlaw AGN model loci, but very close to our Z/Z⊙ = 1.0, F_esc=0.50 filtered continuum model locus. We suggest that this quasar halo is ionized by an unusually soft SED (for an AGN), due to strong filtering of the quasar’s SED by a screen of gas closer to the nucleus, perhaps due to a wide-angle, AGN-driven outflow closer to the nucleus of the galaxy itself. Alternatively, in the case of this quasar one could suppose the presence of a significant contribution from an ionization mechanism that does not produce strong HeII, such as cooling radiation or photoionization by hot, young stars.

With the probable exception of CTS R07.04, we find no need for subsolar gas metallicities, a soft ionizing continuum (including PopIII stars), or enhanced Lyα by scattering to reproduce the Lyα/HeII flux ratios, although strictly speaking these are not ruled out.

As a consistency check, we can calculate the Lyα luminosity expected from the implied value of U and the observed size of a Lyα halo, and then compare against observed values of Lyα luminosity from Borissova et al. (2016). For photoionization of gas the expected Lyα luminosity is given by:

\[ L_{\text{Ly}\alpha} \sim 0.5 \times U^2 \eta_H f_\text{c} \times L_{\text{bol}} \Omega \left( \text{erg s}^{-1} \right) \]

where \( f_\text{c} \) is the covering factor of the gas seen as the ionizing source, \( n_H (\text{cm}^{-3}) \) is the gas density, \( U \) is the ionization parameter, \( r \) (cm) is the distance of the cloud from the ionizing source, \( \eta_H \) is the fraction of the ionizing photons that are able to ionize hydrogen, and \( L_{\text{bol}} \) is the bolometric luminosity of the source. For typical AGN, \( L_{\text{bol}} \) is on the order of \( 10^{46} \text{erg s}^{-1} \).

4 This degeneracy disappears when one compares AGN models against models for ‘normal’ HI regions, where the ionizing stellar populations are cooler and result in substantially weaker HeII emission (see, e.g., Feltre, Charlot & Gutkin 2016; Sobral et al. 2018).

5 We have converted the 2σ limits of Borissova et al. (2016) to 3σ.

6 Our Z/Z⊙ = 1.0, α∼=1.0 curve, not shown in this Figure, just crosses the boundary and reaches down to log Lyα/HeII=1.1.
Fig. 7. Diagnostic diagrams comparing Pop III (heavy orange line) and several AGN photoionization models. The AGN model U-sequences shown here are: $\alpha_0$=-1.5 (thick black line); $\alpha_0$=-2.0 (thin black line); $\alpha_0$=-1.5 with ‘front view’ (‘back-mirror’) (dotted-dashed line); photoionization by our $F_{\alpha_0}$ filtered AGN continuum (dashed line). All models shown in this figure use $Z/Z_\odot=0.01$. See main text for further details. The model loci cover the full range of ionization parameter in our model grid, i.e., -5.55 < log U < 0.25.

$\eta_{Ly\alpha}$ is the ratio of emitted Ly$\alpha$ photons to incident ionizing photons (see Sect. 4.2), and $\Omega$ is the solid angle (in sr) of the central source covered by the ionized gas. The factor 0.5 arises from the multiplication of the constants $4\pi$, $h\nu_{Ly\alpha}$, $c$, and $1/4\pi$ sr. Due to the expected uncertainty in the values of $\eta_{Ly\alpha}$, $f_c$ and $\eta_{Ly\alpha}$, we expect uncertainties in resulting estimates of $L_{Ly\alpha}$ to be at least a factor of $\sim$10. Throughout this work, we assume that the ionizing radiation of the AGN is beamed into a bicone covering a solid angle of $\Omega = 3.7$ sr, corresponding to a pair of ionization cones, each with an opening angle of 90°.

Taking one of the most ‘extreme’ cases from Borisova et al. (2016), Q0042-2627 ($z=3.3$), its Ly$\alpha$/HeII ratio >67 (1.8 in log) would require log U $\leq -4.2$ in our Solar metallicity, $\alpha_0$=-1.5 powerlaw model sequence, corresponding to $\eta_{Ly\alpha}$ ~0.66 (determined from Fig. 2). Although there is likely to be some radial evolution in one or more of $U$, $n_H$, and $f_c$, the exact behaviour of these parameters in a real halo is far from clear. Thus, we adopt constant but characteristic values for each of them. Adopting $n_H$=100 cm$^{-3}$ and $f_c$=0.1 estimated from radio-loud, type 2 quasars at $z \geqslant 2$ (e.g., McCarthy 1993; Villar-Martín et al. 2003), assuming $\Omega = 3.7$ sr, and using the maximum observed radius of Ly$\alpha$ emission $r$ =4.9$\times$10$^{21}$ cm (160 kpc) from Borisova et al. (2016), we estimate $L_{Ly\alpha}$ $\lesssim$1.8$\times$10$^{44}$ erg s$^{-1}$ - consistent with the observed luminosity $L_{Ly\alpha} = 1.7\times10^{44}$ erg s$^{-1}$ in Table 2 of Borisova et al. (2016). The resulting ionizing luminosity of the AGN would be $Q \lesssim 6\times10^{56}$ s$^{-1}$. Note that the values of $L_{Ly\alpha}$ and $Q$ we have derived are both upper limits because our estimate of $U$, from which both are derived, is also an upper limit.

Using instead our model sequence with $Z/Z_\odot = 0.1$ and $\alpha_0$=-1.5, we find log U $\leq -3.8$ and $\eta_{Ly\alpha}$ $\leq 1.25$ from Fig. 2. Leaving $r$, $n_H$, $f_c$ and $\Omega$ unchanged, we obtain $L_{Ly\alpha} \lesssim 9\times10^{44}$ erg s$^{-1}$ - still consistent with the observed luminosity. Using the same methodology, we also find a similar level of consistency between

---

7 The solid angle of an ionization cone with its apex at the position of the central ionizing source is given by $\Omega = 2\pi (1 - \cos \beta)$ sr, where $\beta$ is the half opening angle of the cone.
the expected and observed $L_{\text{L} \alpha}$ values for the 10 other quasars from Borisova et al. which show ‘extreme’ Ly$\alpha$/HeII ratios.

These calculations serve to illustrate the plausibility of very low U, possibly coupled with low gas metallicity, to explain the ‘extreme’ Ly$\alpha$/HeII ratios measured by Borisova et al. (2016). However, we stress that our consistency check is not intended as proof of a particular value for any of the parameters in Equation (1).

It seems particularly plausible that the large-scale gas halos of high redshift quasars such as these would have low gas metallicity, since the central galaxy is expected to be fed by cold streams of pristine or very low metallicity gas from the cosmic web (e.g. Goerdt et al. 2015; Vernet et al. 2017). However, observations of the halos of high-z quasars appear to show such halos are already polluted with metals (e.g., Humphrey et al. 2013; Prochaska et al. 2013).

The detectability of Ly$\alpha$ from extended gas around high-z AGN, and the use of this emission for improving our understanding of galaxy evolution, continue to be key topics in extragalactic astrophysics (e.g., Haiman & Rees 2001; Villar-Martín et al. 2003; Borisova et al. 2016). Our new modeling results have interesting implications for the detectability of Ly$\alpha$ halos associated with high-z AGN. Firstly, cold gas around a quasar should be considerably more luminous in Ly$\alpha$, and thus easier to detect, if the gas has a lower metallicity and/or if it sees a harder ionizing spectrum. We also suggest that the high detection rate of extended Ly$\alpha$ halos in quasars at high-z (e.g. Borisova et al. 2016) may be due to this effect. In addition, lower gas metallicity and a harder ionizing spectrum could result in apparently larger Ly$\alpha$ halos, as the correspondingly higher $\eta_{\text{Ly} \alpha}$ would make faint, outer regions more detectable.

6. Summary

We have used the modeling code MAPPINGS Ie to explore potential mechanisms to produce enhanced Ly$\alpha$ relative to HeII and other emission lines in extended nebulae photoionized by powerful AGN. Our grid of photoionization models cover a substantial range in ionization parameter U, the gas metallicity and the shape of the ionizing continuum, and considers two different electron energy distributions and cloud viewing angles.

We are able to produce ‘extreme’ Ly$\alpha$/HeII flux ratios using parameters appropriate to extended Ly$\alpha$ emitting halos around high-z quasars. We recover the previously reported Ly$\alpha$/HeII-enhancing effects of low metallicity (e.g., Villar-Martín et al. 2007), low U (e.g. Arrigoni Battaia et al. 2015a,b), and cloud perspective (Villar-Martín, Binette & Fosbury 1996). Our grid reaches much lower values of U than previous studies by Arrigoni Battaia et al. (2015a,b), and results in even higher values of Ly$\alpha$/HeII.

As expected from previous studies (e.g., Humphrey et al. 2008; Arrigoni et al. 2015b), the spectral index of the ionizing powerlaw affects the Ly$\alpha$/HeII ratio, with a softer spectrum (i.e., $\alpha=2.0$) resulting in higher Ly$\alpha$/HeII values. We also find that using a pre-filtered ionizing spectrum can result in extremely high Ly$\alpha$/HeII ratios, with values reaching as high as log Ly$\alpha$/HeII = 4.4 for heavily filtered continua ($F_{\text{esc}} = 0.28$) and low ionization parameter (log U = -5.55).

The Ly$\alpha$/HeII-enhancing effects described above can have a cumulative impact on the Ly$\alpha$/HeII ratio when two or more of the effects are present in our models. For instance, combining a softer ionizing continuum, a lower gas metallicity and/or low ionization parameter can result in a significantly higher Ly$\alpha$/HeII ratio than would have otherwise be produced using only one of the above. The most ‘extreme’ model in our grid, which uses log U = -5.55, a heavily filtered continuum ($F_{\text{esc}}=0.28$), low gas metallicity ($Z/Z_\odot=0.01$) and a maximal contribution from an HI ‘back-mirror’ produces log Ly$\alpha$/HeII = 4.6.

In addition to studying the variation of the Ly$\alpha$/HeII flux ratio, we have also examined the variation in the ratio of emitted Ly$\alpha$ photons to incident ionizing photons, $\eta_{\text{Ly} \alpha}$. The value of $\eta_{\text{Ly} \alpha}$ ranges from 0.58 to 2.7 in our model grid, deviating substantially from the expected pure-recombination value $\eta_{\text{Ly} \alpha}=0.66$ for optically-thick gas (e.g. Gould & Weinberg 1996). This variation is driven by differences in the electron temperature and H neutral fraction between models, with higher temperature and higher H neutral fraction each resulting in higher rates of collisional excitation of Ly$\alpha$. In some of our low metallicity models ($Z/Z_\odot = 0.1$) we obtain $\eta_{\text{Ly} \alpha} > 1.4$, indicating that collisional excitation is the main channel of Ly$\alpha$ production.

In addition, including the effects of an HI ‘back-mirror’ can increase the observational $\eta_{\text{Ly} \alpha}$, by a factor of up to 2, leading to (effective) $\eta_{\text{Ly} \alpha}$ values as high as 5.3. Generally speaking, lower gas metallicities, and/or the use of a harder or filtered ionizing SED, results in higher values of $\eta_{\text{Ly} \alpha}$. An important implication is that Ly$\alpha$ halos ought to be easier to detect if they have lower gas metallicity or are ionized by a harder or filtered ionizing SED. In principle, this could lead to selection biases in surveys to detect Ly$\alpha$ halos and blobs at high redshift.

Interestingly, we have also found that using k-distributed electron energies ($k=20$) instead of Maxwell-Boltzmann-distributed energies can result in slightly enhanced production of Ly$\alpha$ photons, with a 10-20 per cent enhancement in $\eta_{\text{Ly} \alpha}$ at high gas metallicity ($Z/Z_\odot=1.0$ and moderate to low ionization parameter (log U ≤ -2). However, at low gas metallicity ($Z/Z_\odot \leq 0.1$) and high U (log U ≥ -1.4) there is a slight (~10 per cent) drop in $\eta_{\text{Ly} \alpha}$. A future study will examine in greater detail the impact of k-distributed electron energies on the emission line spectrum of the narrow line region or Ly$\alpha$ halo of AGN (Morais et al., in prep.).

We have also shown that the extreme Ly$\alpha$ and HeII emission line ratios of the extended Ly$\alpha$ halos of z~3.5 quasars studied by Borisova et al. (2016) are consistent with AGN-photoionization of gas with moderate to low metallicity (e.g. $Z/Z_\odot<0.01$) and/or low ionization parameter (e.g. log U ≤ -4), without requiring exotic ionization/excitation mechanisms such as PopIII stars or extreme transfer effects. In the case of the most ‘Ly$\alpha$-extreme’ quasar from this sample, CTS R07.04 at z=3.35, we find that its Ly$\alpha$, HeII and CIV flux ratios are consistent with gas photoionized by a moderately filtered ionizing SED ($F_{\text{esc}} \sim 0.5$). We speculate that such filtering may occur in a wide-angle, AGN-driven outflow nearer the nucleus.

Finally, we find that Ly$\alpha$/HeII alone is insufficient to discriminate between ionization by Pop III stars and an AGN. However, we find that using this ratio together with Ly$\alpha$/H$\beta$ can provide a clean separation between Pop III and AGN photoionization, even if the gas illuminated by the AGN has very low gas metallicity ($Z/Z_\odot < 0.01$).

Appendix A: Alternate version of Fig. 5

Here we show an alternate version of Fig. 5 showing the same model loci, but plotted as a function of \( U^* = U / F_{esc} \) to aid comparison with our unfiltered models.

Fig. A.1. The impact of using a filtered ionizing continuum instead of a simple powerlaw on the observed values of Lyα/HeII, Lyα/Hβ and \( \eta_{Lyα} \). In order that the curves be aligned, the models are plotted as a function of \( \log U^* \), where \( U^* = U / F_{esc} \). In the upper panel, the \( U^* \)-sequences using a filtered ionizing continuum are labeled with their respective value of \( F_{esc} \). \( U^* \)-sequence loci which use our default powerlaw of \( \alpha = -1.5 \) are labeled ‘1.0’ because the input SED is unfiltered. The dot-dashed curve (on the right of the upper panel) shows the locus of our sequence in \( U^* \) that uses \( F_{esc} = 0.28, Z/Z_\odot = 0.01, \alpha = -1.5 \) and the ‘front view’, to illustrate the combined effect of low \( U^* \), low gas metallicity, a heavily filtered ionizing continuum, and a ‘back-mirror’. For each combination of \( U^* \) and \( Z/Z_\odot \), a lower \( F_{esc} \) results in a lower Lyα/HeII.
