Landau’s Fermi liquid theory provides the basis for our understanding of most conventional metals. A particularly interesting application of Fermi liquid theory is to intermetallic compounds containing localized spin moments on $d$ or $f$ orbitals and additional bands of conduction electrons. These systems are conveniently modelled by the Kondo lattice Hamiltonian, with exchange interactions between the local moments and the conduction electrons, and possibly additional exchange couplings between the local moments themselves. These display metallic “heavy” Fermi liquid phases (albeit with large quasiparticle effective masses and other renormalizations) in addition to phases with magnetic or superconducting long-range order. The quantum phase transitions between the various phases are currently subject of intense research activities. For instance the transition between the heavy Fermi liquid and a magnetic metal exhibits a number of interesting non-Fermi liquid phenomena which have not yet found a consistent theoretical explanation. For particular interest in heavy electron physics is the issue of the topology of the Fermi surface, and how it evolves across various phase boundaries. It is believed by some workers in the field that this issue is at the heart of the non-Fermi liquid physics observed near heavy electron critical points. Our understanding of such matters is rather primitive – clearly it would help to build more intuition about such phenomena. In this paper we consider a paradigmatic model that illustrates some of these issues and the associated difficulties.

We consider bilayer Kondo systems, consisting of pairs of identical two-dimensional layers with local moments and conduction electrons. We assume that the conduction electrons cannot hop between the two layers. As argued below, such bilayer systems allow for two different paramagnetic Fermi liquid phases. These two phases are sharply distinct: the distinction is in the topology of the Fermi surface. In one case the Fermi surface may loosely be dubbed “large” – physically this happens when the local moments participate in the Fermi surface. In the other case the local moments are not part of the Fermi sea and the Fermi surface may loosely be dubbed “small”. We emphasize that Luttinger’s theorem is satisfied in both phases – however the Fermi surface topology is different, implying that the two phases cannot be smoothly connected to each other. We argue below that a novel ordered phase generically intervenes in between the two phases. This ordered state involves spontaneous development of interlayer coherence despite the absence of any direct single particle hopping. The interlayer coherence may either be in a particle-hole (i.e. exciton) condensate or in a particle-particle condensate. The former is analogous to states much discussed in bilayer quantum Hall structures while the latter is a bilayer superconductor with Cooper pairs shared between the two layers. At finite temperatures above the ordered phase we expect signatures of critical behavior associated to strong Fermi surface fluctuations.

To be specific, consider the Hamiltonian:

$$H = - \sum_{(jj')\sigma\alpha} t_{jj'} c_{j\alpha}^\dagger c_{j'\sigma} + \frac{J_K}{2} \sum_{j\sigma'\alpha} \tilde{S}_{j\alpha} \cdot \tau_{\sigma\sigma'} c_{j\alpha}^\dagger + \sum_{(jj')\alpha} J_{jj'} \tilde{S}_{j\alpha} \cdot \tilde{S}_{j'\alpha} + \sum_{\mathbf{j} j_{1} j_{2}} J_{\mathbf{l}} \tilde{S}_{j_{1}} \cdot \tilde{S}_{j_{2}}. \quad (1)$$

The lattice sites are labelled with $j$ in each layer, and $\alpha = 1, 2$ is the layer index. The local moments $\tilde{S}_{j\alpha}$ are $S = 1/2$ spins, and the conduction electrons $c_{j\alpha}$ ($\sigma = \uparrow \downarrow$) hop on the sites $j$, $j'$ of some regular lattice in $d$ spatial dimensions ($d = 2$ for most what follows) with amplitude $t_{jj'}$. $J_K > 0$ are the Kondo exchanges, $I_{jj'}$ denote explicit short-range Heisenberg interactions within each plane of local moments, and $J_{\mathbf{l}}$ is the interlayer exchange interaction. A chemical potential for the $c_\sigma$ fermions which fixes their density at $\rho_c$ per unit cell of the ground state is implied.

The absence of any direct interlayer hopping implies that the number of electrons in each layer is separately...
conserved. The corresponding symmetry plays an important role in our analysis. In contrast, only the total spin of both layers is conserved. For situations where the ground state of the system is a Fermi liquid, it can be characterized by its Fermi volume, i.e., the volume in momentum space enclosed by the Fermi surface, which is defined by the location of poles in the conduction electron Green’s function at the Fermi level. The Fermi liquid phase of a single-layer Kondo system is known to have a Fermi volume, $V_{FL}$, counting all electrons in the unit cell, i.e., both conduction electrons and local moments, as determined by the Luttinger theorem:  

$$V_{FL} = K_d \rho_T \text{(mod 2)}. \quad (2)$$

Here $K_d = (2\pi)^d / (2v_0)$ is a phase space factor, $v_0$ is the volume of the unit cell of the ground state, $\rho_T = n_t + \rho_c$ is the total density of electrons per volume $v_0$, and $n_t$ (an integer) is the density of local moments per volume $v_0$.

For Fermi liquid phases in the present bilayer system, the Fermi volume can be defined separately for both layers as the number of electrons in each layer is separately conserved. But what about Luttinger’s theorem? By an extension of the argument in Ref. 4, it is easy to see that only the total volume of the Fermi surface of both layers together is constrained. Specifically we have

$$V_{FL}^{(1)} + V_{FL}^{(2)} = K_d \left( \rho_T^{(1)} + \rho_T^{(2)} \right) \text{(mod 2)}. \quad (3)$$

Here the superscript 1, 2 is a layer index. Thus individual Fermi volumes of the two layers (though well-defined) are not necessarily required to match the total electron count in their layer.

**Phase diagram.** Let us start with discussing various limits in parameter space. States without magnetic long-range order can be conveniently discussed keeping $I = 0$. We also assume the conduction band to be away from perfect particle-hole symmetry to avoid non-generic nesting effects.

For large Kondo coupling, $J_K \gg J_\perp$, each local moment $\vec{S}_{j\alpha}$ will be Kondo screened by the conduction electrons in layer $\alpha$. Thus, a heavy Fermi liquid is formed separately in each layer, with a large Fermi volume per layer – we dub this FL-L phase. The effect of a small non-zero $J_\perp$ is to generate spin correlations between the two Fermi liquids. These will in general lead to innocuous renormalizations of the Fermi liquid parameters.

For dominating interlayer exchange, $J_\perp \gg J_K$, the local moments form interlayer singlets. For $J_K = 0$ the conduction electrons in each layer form a Fermi liquid with a small Fermi volume per layer (FL-S phase). Finite $J_K$ can be treated perturbatively, leading to spin-singlet couplings of order $J_K^2 / J_\perp$ between the two Fermi liquids, which again only lead to unimportant renormalizations of Fermi liquid parameters.

Note that either Fermi liquid satisfies the generalized Luttinger theorem in Eq. 3. Nevertheless the topologies of the Fermi surfaces are quite different. Indeed it is not possible to smoothly go from FL-S to FL-L without a phase transition. To see this note that the interlayer exchange symmetry is preserved in both phases: this symmetry guarantees that the volume (and shape) of the total Fermi volume is quantized. For the individual Fermi volumes $V_{FL}^{(1,2)}$ must also be quantized. However they are quantized to two different values in the two phases. In FL-L,

$$V_{FL}^{(1)} = V_{FL}^{(2)} = K_d (\rho_c + 1) \quad (4)$$

while in FL-S

$$V_{FL}^{(1)} = V_{FL}^{(2)} = K_d \rho_c. \quad (5)$$

Thus the two phases cannot be smoothly connected.

As function of $J_K / J_\perp$ the system evolves from FL-S to FL-L which involves a change in the quantized value of the Fermi surface volume per layer: how does this happen? Besides a direct first-order transition, we show below that intermediate ordered phases which break some symmetry are very natural. An example is an intermediate phase with spontaneous interlayer phase coherence (COH), the order parameter being $\phi = \sum_{j,\alpha} \langle c_{j\alpha 1}^\dagger c_{j\alpha 2} \rangle$. This phase breaks the separate conservation of electron number in the individual layers, while preserving total electron number conservation. An alternate possibility is an interlayer superconductor which breaks the symmetry of total electron number conservation while preserving conservation of the difference of the electron number in the two layers. In our bilayer system, it does not seem possible to have a direct second-order “Fermi-volume-changing” transition between the two Fermi liquids. Paranthetically, we note that finite exchange inter-
action \( I \) can lead to various phases with magnetic long-range order – these will not be considered further.

**Mean-field theory.** We use a fermionic auxiliary-particle representation of the local moments:

\[
\tilde{S}_{j\alpha} = \frac{1}{2} \sum_{\sigma} f_{j\sigma\alpha}^\dagger f_{j\sigma\alpha} + h.c.
\]

where \( f_{j\sigma\alpha} \) describes a spinful fermion destruction operator at site \( j \). As usual, mean-field equations are obtained by decoupling the various interaction terms, resulting in the mean-field Hamiltonian \( H_{mf} \):

\[
H_{mf} = \sum_{k\sigma} \epsilon_k c_{k\sigma}^\dagger c_{k\sigma} + \sum_{j\sigma} \chi_j (f_{j\sigma1}^\dagger f_{j\sigma2} + h.c.) + \sum_{j\sigma\sigma'} \mu_{f\sigma\sigma'} f_{j\sigma1}^\dagger f_{j\sigma2} - b_\alpha (c_{k\sigma2}^\dagger f_{k\sigma1} + h.c.).
\]

\( \epsilon_k \) is the conduction band dispersion resulting from the \( t_{jj'} \), and we have assumed \( I = 0 \). The mean-field parameters are determined by the saddle-point equations

\[
1 = \sum_{\sigma} \langle f_{j\sigma1}^\dagger f_{j\sigma2} \rangle,
\]

\[
2b_\alpha = J_K \sum_{\sigma} \langle c_{j\sigma1}^\dagger f_{j\sigma2} \rangle,
\]

\[
2\chi_j = J_{\perp} \sum_{\sigma} \langle f_{j\sigma1}^\dagger f_{j\sigma2} \rangle.
\]

The above mean-field theory can be justified by generalizing the spin symmetry from SU(2) to SU(\( N \)) and taking the limit \( N \to \infty \). (Very similar results are obtained using a Sp(\( N \)) generalization). Low-energy fluctuations around the mean-field solution are phase fluctuations of the mean-field order parameters, i.e., local U(1) gauge fluctuations.

The FL-L phase with Kondo screening is described by non-zero expectation values \( \langle c_{j\sigma1}^\dagger f_{j\sigma2} \rangle \) at the mean-field level. The FL-S phase with interlayer singlet formation of the local moments has non-zero \( \langle f_{j\sigma1}^\dagger f_{j\sigma2} \rangle \). Note that both quantities involve the auxiliary \( f \) particles and are thus not physical observables, i.e., they cannot sustain expectation values once gauge fluctuations are included.

Consider now a state where both \( \langle f_{j\sigma1}^\dagger f_{j\sigma2} \rangle \) and \( \langle c_{j\sigma1}^\dagger c_{j\sigma2} \rangle \) are non-zero. Then it follows that \( \phi = \langle c_{j\sigma1}^\dagger c_{j\sigma2} \rangle \neq 0 \) – this gauge-invariant complex quantity is a physical observable, which breaks a physical U(1) symmetry and characterizes a phase with spontaneous interlayer phase coherence! For the two-dimensional system under discussion, small finite temperature will lead to quasi-long-range order, which disappears in a finite-temperature Kosterlitz-Thouless transition. No other finite-temperature phase transitions are expected, as there are no broken symmetries in both FL phases. The resulting schematic phase diagram is in Fig. 1. We have performed a fully self-consistent solution of the mean-field equations for various sets of parameters, and a sample mean-field phase diagram is in Fig. 2.

**Interlayer coherence phase.** We now discuss a few properties of the interlayer coherence phase. It is characterized by the presence of a particle-hole (i.e. excitonic) condensate, with the expectation value \( \phi = \langle c_{j\sigma1}^\dagger c_{j\sigma2} \rangle \) being non-zero, in the absence of explicit interlayer hopping. Thus there will be a spontaneous bilayer splitting in the electronic structure, i.e., the electrons in both layers will spontaneously form a bonding and an antibonding band – this feature should be observable in high-resolution photoemission experiments. The COH phase will have an electronic Fermi surface that satisfies the generalized Luttinger theorem in Eq. (9). However, this Fermi surface will be shared by electrons in the two layers – in the sense that the quasiparticle states are admixtures of electrons from both layers. Thus the notion of two distinct quantized Fermi surfaces associated with either layer is no longer meaningful. The Fermi surface evolution from FL-L to FL-S is illustrated in Fig. 3. The broken U(1) symmetry implies a linearly dispersing collective Goldstone mode with quantum numbers (total) charge 0 and spin 0.

The present interlayer coherence phase is the zero-field analogue of the corresponding phase in bilayer quantum Hall systems. In the quantum Hall context this type of order has also been dubbed pseudospin ferromagnetism, where the pseudospin degree of freedom refers to the layer index of a given electron.

**Fluctuation effects.** As argued above, both Fermi liquid phases are stable w.r.t. fluctuations, their main effect being the restoration of the U(1) gauge symmetry which is broken at the mean-field level; this also implies the absence of any finite-temperature transition above the FL phases.
In the interlayer coherence phase amplitude fluctuations of the mean-field parameters will be gapped. An action for the phase fluctuations can be formally obtained by integrating out all fermions from the problem; the result is easily seen to generate the phase mode of the order parameter with a linear dispersion.

Interlayer superconductivity. It is possible to imagine other instabilities near the FL – FL-S transition. One is the formation of coherence in the particle-particle sector, i.e., interlayer superconductivity (with a charge-2 condensate). At the mean-field level, this can be captured by a mixed decoupling, namely the $J_K$ term with a particle-hole field $b$ and the $J_\perp$ term with a particle-particle field $\chi$ (or vice versa). Then, the phase with both $b$ and $\chi$ non-zero will have a non-vanishing expectation value $\langle c_{j1} c_{j2} \rangle$, representing interlayer superconducting pairing, i.e., Cooper pairs shared by the two layers, with s-wave orbital symmetry. We note that the inclusion of Coulomb repulsion in the model will favor the interlayer coherence phase over the interlayer superconducting phase.

Discussion. We have described the physics of bilayer Kondo lattice systems which contain the competition between the Kondo effect and intermoment exchange. Two distinct Fermi liquid phases can occur upon varying the ratio of the Kondo interaction and the interlayer coupling between the local moments. These Fermi liquids may be loosely distinguished by whether or not the local moments participate in the Fermi surface. A more precise distinction is provided by the topology of their Fermi surfaces as captured by the notion of the quantized value of the Fermi volume per layer. We have argued that a phase with a form of exotic order, namely spontaneous interlayer coherence in either the particle-hole or the particle-particle channel, generically intervenes between the two Fermi liquids. Experimental observation of the former phase may be possible in angle-resolved photoemission where a spontaneous splitting between the bands of the two layers (or a splitting larger than that predicted by band theory) will be observed.

The finite-temperature properties in the transition region between the two phases are particularly interesting. In the region above the phase transition to the ordered phase the behavior is that of a metal with an undecided Fermi volume per layer, i.e., the Fermi surface will be strongly fluctuating. We expect that the properties will be non-Fermi liquid like and possibly similar to that observed in various “strange metals” such as near heavy electron magnetic critical points or in the optimally doped cuprates. Interestingly, signatures of fluctuating Fermi surfaces near quantum criticality have been experimentally detected, e.g., in the heavy electron metal YbRh$_2$Si$_2$ [12–14] and in the bilayer ruthenate Sr$_3$Ru$_2$O$_7$ [15, 16]. Developing a theory of strange metal states is a major challenge in condensed matter physics – we hope that the bilayer systems discussed here can contribute in some way.
