The risk of dementia in adults with abdominal aortic aneurysm

Hyung-jin Cho1, Ju-hwan Yoo2, Mi-hyeong Kim1, Kyung-jai Ko3, Kang-woong Jun4, Kyung-do Han5,6 & Jeong-kye Hwang1,6*

Abdominal aortic aneurysm (AAA) and dementia have similar epidemiological profiles and common pathogenic mechanisms. However, there have been few studies on the link between these two diseases. For this study, information from 2009 to 2015 was extracted from the Korean National Health Insurance system database. A total of 15,251 participants with a new diagnosis of AAA was included. Propensity score matching by age and sex with patients in whom AAA was not diagnosed was used to select the control group of 45,753 participants. The primary endpoint of this study was newly diagnosed dementia (Alzheimer’s disease (AD), vascular dementia (VD), or other type of dementia). The incidence of dementia was 23.084 per 1000 person years in the AAA group, which was higher than that of the control group (15.438 per 1000 person years). When divided into AD and VD groups, the incidence of AD was higher than that of VD, but the HR of AAA for occurrence of dementia was higher in VD (1.382 vs. 1.784). Among the various risk factors, there was an interaction of age, hypertension, and history of cardiovascular disease with incidence of dementia (p < 0.05). In the presence of hypertension, the HR for occurrence of dementia was high according to presence or absence of AAA (1.474 vs 1.165). In addition, this study showed higher HR in the younger age group (age < 65) and in the group with no history of cardiovascular disease (1.659 vs. 1.403, age) (1.521 vs. 1.255 (history of cardiovascular disease)). AAA was associated with increased risk of dementia regardless of AD or VD, even after adjusting for several comorbidities. These findings indicate that follow-up with AAA patients is necessary for early detection of signs and symptoms of dementia.

Dementia is acquired loss of cognition in multiple cognitive domains that is sufficiently severe to affect social or occupational function1. The pooled point prevalence of dementia per 1000 in 23 community setting studies was 48.62, and the incidence rate of dementia per 1000 person-years was 17.18 in the community-only setting. The three most common types of dementia in order of prevalence are Alzheimer’s disease (AD), vascular dementia (VD), and Lewy body dementia. Age is the most important risk factor for dementia, with prevalence doubling every 5 years after age 65; the prevalence is increased from 2–3% in those 65–69 years to 30% among individuals older than 80.

An abdominal aortic aneurysm (AAA) is a permanent localized dilatation of the abdominal aorta that exceeds the normal diameter by 50%, or > 3 cm. The mean annual incidence of new AAA diagnoses in Western populations is 0.4–0.67%. Age is a risk factor for AAA, and there are similarities in epidemiological profiles between dementia and AAA including smoking, hypertension, obesity, and hyperlipidemia2–4.

Until recently, dementia has been considered neither preventable nor treatable, but recent clinical trials assessing the effects of lifestyle modification in dementia offer hope, showing that 35% of AD risk is modifiable2–6. These modifiable factors generally do not apply to AAA; however, given the similarity of their epidemiological profiles and the many common pathogenic mechanisms7, the possibility of a link between the two can be considered.

Therefore, in this study, we investigated the effects of the presence of AAA on the incidence rate of dementia during a 7-year period in Korean using a Korean National Health Insurance Service (NHIS) database.

**Methods**

**Data source.** The Korean National Health Insurance (NHI) system consists of two major health care programs for universal coverage of all residents of Korea: NHI and Medical Aid (MA). Approximately 97% of the population is covered by NHI, and the remaining 3% is covered by MA. The NHIS provides biannual health examinations for all insured Koreans and maintains an extensive data set of Koreans that includes patient demographics, medical treatment and procedures, and disease diagnoses according to the International Classification of Disease, 10th editions (ICD-10). For this study, information from 2009 to 2015 was extracted from the NHIS database.

**Sampled patients.** Patients in the database who were newly diagnosed with AAA between 2009 and 2015 were enrolled (n = 45,767). The AAA group was defined as patients diagnosed with AAA codes (I71.3–I71.6, I71.8, and I71.9) more than twice at an outpatient department in the past year, who had been hospitalized with one of these AAA codes more than once, or who had undergone aneurysm repair surgery such as open surgical aneurysm repair (OSAR) or endovascular aneurysm repair (EVAR) defined by with the codes (O0223, O0224, O0234, M6611, and M6612). We excluded patients who had not undergone a health examination within 2 years prior to diagnosis of AAA (n = 26,121), were younger than 40 years (n = 431), had data missing (n = 250), or had a previous diagnosis of dementia (n = 1024). Among the remainder, a group of patients who were followed for more than one year was selected (n = 15,251). To select the control group, with a number of participants three times larger than that of the patient group (n = 45,767), we used propensity score matching by age and sex with patients in whom AAA was not diagnosed (Fig. 1). The primary endpoint of this study was newly diagnosed dementia (AD, VD, or other type of dementia).

**Data collection and definition.** We collected baseline data from the NHIS database of age, sex, smoking status, alcohol consumption, physical activity, waist circumference, body mass index (BMI), and income level. Data about comorbidities, including hypertension, diabetes, dyslipidemia, chronic kidney disease (CKD),

---

**Figure 1.** Enrollment flow chart.
and history of cardiocerebrovascular disease (CVD), also were collected. Smoking status was classified as non-
smoker, ex-smoker, and current smoker. Alcohol consumption was classified as heavy drinker when the average
daily alcohol intake was 30 g or more, mild to moderate drinker when the individual consumed less than 30 g
daily, and non-drinker. Physical activity was divided into two groups, one performing moderate exercise more
than 5 days per week or vigorous exercise more than 3 days per week; and all others were classified into the
second group. Income level was classified into a group that received medical aid and was in the bottom 20% of
income and a group of all others. Comorbidities were defined as follows: DM [codes (E11-14 with antidiabetic
medication) or (fasting blood sugar ≥ 126)], hypertension [codes (110-13 and I-15 with antihypertensive medica-
tion) or (SBP ≥ 140) or (DBP ≥ 90)], dyslipidemia [(code E78 with antihyperlipidemic medications) or (total
cholesterol ≥ 240)], CKD (eGFR < 60), and history of CVD [cerebrovascular disease codes (I60-64) and cardio-
vascular disease codes (I20-25)]. Finally, dementia was defined as follows: AD [codes (F00, and G30)], VD [code
(F01)], other dementia [codes (F02, F03, and G31)] with one or more medications for dementia (donepezil,
rivastigmine, galantamine, or memantine). When there were codes for both AD and VD, the main diagnosis
was selected as the final diagnosis. If there was neither AD nor VD as a main diagnosis up to the second claim
database, the diagnosis was defined as “other dementia”. This study is approved by the Institutional Review Board
of The Catholic University of Korea, Eunpyeong St. Mary’s Hospital, Seoul, Korea (approval no. PC20ZISI0145).
All methods were performed in accordance with the relevant guidelines and regulations approved by the Insti-
tutional Review Board of The Catholic University of Korea, Eunpyeong St. Mary’s Hospital, Seoul, Korea. Also,
Informed consent was waived by the Institutional Review Board of the Catholic University of Korea, Eunpyeong
St. Mary’s Hospital, Seoul, Korea because all analysis used anonymous data.

Statistical analysis. Continuous variables are presented as mean ± standard deviation, and categorical
variables are presented as number (percentage). To compare characteristics between patient and control groups,
Student’s t-test was used for continuous variables and the chi-square test or Fisher’s exact test for categorical vari-
ables. The incidence rates of dementia are presented per 1000 person-years. Multivariate Cox regression models
were used to evaluate the association of absence or presence of AAA with incidence of new-onset dementia.
Model 1 examined the unadjusted hazard ratios (HRs). Model 2 was adjusted for age, sex, income level, presence
diabetes, hypertension, and dyslipidemia. In Model 3, smoking status, alcohol consumption, exercise status,
and BMI were added; and history of CVD was added to Model 4. The cumulative incidence of dementia accord-
ing to presence of AAA was calculated using Kaplan–Meier curves; the log-rank test was performed to analyze
differences among the groups. Statistical significance was set at p < 0.05. All statistical analyses were performed
using SAS version 9.4 (SAS Institute Inc., Cary, NC, USA.) and the R Project for Statistical Computing version
3.3.

Results
Baseline characteristics according to presence of AAA. The characteristics of subjects by presence of
AAA are presented in Table 1. Hypertension, and dyslipidemia are known risk factors for AAA and were more
common in the AAA group. Also, there were more smokers in the AAA group, and BMI and abdominal circum-
ference were higher in the AAA group. In addition, history of CVD was significantly higher in the AAA group,
but alcohol consumption and exercise level were lower in the AAA group.

Incidence of dementia. The incidence of dementia was 23.084 per 1000 person years in the AAA group,
which was higher than that of the control group. When all models were applied respectively, the incidence rate
remained significantly higher in the AAA group; and the hazard ratio was 1.516, 1.625, 1.568, and 1.422 for
models 1 through 4, respectively. When divided into AD and VD groups, the incidence of AD was higher than
that of VD, but the HR of AAA for dementia was higher in the VD group (1.382 vs. 1.784 in model 4). (Table 2).

The Kaplan–Meier plot shows a comparison with the control group. All types of dementia occurred more
frequently in the AAA group, which also was observed when divided into AD and VD groups (log rank test p
value < 0.001) (Fig. 2).

Interactions with AAA on occurrence of dementia. Among the factors, there was interaction of age,
hypertension, and history of cardiovascular disease with AAA (p < 0.05). In the presence of hypertension, the
HR for occurrence of dementia was high according to presence or absence of AAA (1.474 vs 1.165). These results
were observed in the younger age group and in the group with no history of cardiovascular disease [1.659 vs.
1.403 (age), 1.521 vs. 1.255 (history of cardiovascular disease)] (Supplemental Table 1).

Discussion
The current social expenditure of dementia is US$ 604 billion/year worldwide, and it is projected that the number
of dementia patients will triple by 2050. Therefore, it is possible to estimate the global socio-economic impact
of dementia⁶,⁸. For treatment of dementia, a variety of pharmacologic and non-pharmacologic approaches has
been attempted, but their efficacy has not been confirmed. Rather, treatment is focused on symptom control,
and prevention is considered the top priority¹,²,⁶,¹⁰. A recent review by Livingston and coworkers suggests that
approximately 35% of dementia is attributable to nine modifiable risk factors⁷. To prevent dementia, it is neces-
sary to manage these risk factors including diabetes, hypertension, smoking, and obesity.

These risk factors are also related to AAA in various mechanisms and there are both commonalities and
differences in the mechanisms by which the factors act on the disease¹¹⁰. The relationship between dementia
and AAA was verified through this study, which might be due to the association of these risk factors. Although
this effect cannot be completely offset, it was controlled as much as possible by analyzing through model that
was adjusted using various variables including these risk factors, and there was a relationship between AAA and dementia. Since the association between these two diseases has not been revealed, we would like to propose our hypothesis through a pathophysiological approach. The first such association is related to atherosclerosis. Traditionally, it was thought that AAA develops as a pathological response to aortic atherosclerosis. Until half a century ago, the term "atherosclerotic aneurysm" was used. This view still is favored by some researchers. Atherosclerotic plaque growth leads to a compensatory arterial response. In other words, due to arterial narrowing, hemodynamic changes such as those in shear stress occur. The endothelium detects this and changes the phenotype of vascular smooth muscle cells, allowing remodeling through secretion of proteolytic enzymes such as metalloproteinase (MMP). Atherosclerosis typically is widespread throughout the vasculature, and the carotid artery is not exempt. Carotid atherosclerosis

### Table 2. Hazard ratio of AAA for incidence of dementia. AAA Abdominal aortic aneurysm. Model 1 adjusted for age and sex, Model 2 adjusted for age, sex, income level, diabetes, hypertension, and dyslipidemia. Model 3 adjusted for age, sex, income level, diabetes, hypertension, dyslipidemia, smoking status, alcohol consumption, exercise status, and BMI. Model 4 adjusted for age, sex, income level, diabetes, hypertension, dyslipidemia, smoking status, alcohol consumption, exercise status, BMI, and history of CVD.

| AAA               | No               | Event | Duration | Rate | Model 1 | Model 2 | Model 3 | Model 4 |
|-------------------|------------------|-------|----------|------|---------|---------|---------|---------|
| All types of dementia | 45,753          | 1324  | 209,489.14 | 15.4376 | 1 | 1 | 1 | 1 |
| Yes               | 15,251          | 1432  | 62,034.29  | 23.084 | 1.516(1.424,1.613) | 1.625(1.523,1.734) | 1.568(1.468,1.674) | 1.422(1.326,1.525) |
| Alzheimer's disease | 45,753          | 2611  | 209,489.14 | 12.4637 | 1 | 1 | 1 | 1 |
| Yes               | 15,251          | 1090  | 62,034.29  | 17.5709 | 1.433(1.335,1.538) | 1.548(1.438,1.666) | 1.495(1.388,1.61)  | 1.382(1.277,1.496) |
| Vascular dementia | 45,753          | 332   | 209,489.14 | 1.58481 | 1 | 1 | 1 | 1 |
| Yes               | 15,251          | 213   | 62,034.29  | 3.43358 | 2.18(1.835,2.59)  | 2.233(1.865,2.672) | 2.136(1.781,2.561) | 1.784(1.467,2.169) |
and stiffness consequently cause brain microcirculation transformation and increase blood–brain barrier (BBB) permeability, leading to cognitive impairment. Similarly, associations between descending thoracic aortic plaque and acceleration of brain aging have been demonstrated, and trends in accelerated progression of brain atrophy and progression of cerebrovascular lesions have been reported.

Figure 2. Kaplan–Meier plot for incidence of dementia in patients with AAA.
The second association is inflammation and matrix degradation. Aortic inflammation is believed to lead to destruction of aortic media and vascular smooth muscle cell apoptosis and dysfunction. Release of a range of proteolytic enzymes, such as MMP and cysteine proteases, produces reactive oxygen, cytokines, and related products. The tissue inhibitors of MMP (TIMP) are increased in the wall of the aneurysm; however, the balance between TIMP and MMP seems to favor proteolysis, and elastin and collagen fibers are degraded. Also, due to the paracrine effect of VSMC, a protective effect is needed to maintain homeostasis from proteolysis and inflammatory reactions. However, VSMC apoptosis prevents this protective effect. These MMPs (MMP-2) induce breakdown of the BBB, disrupt oxidative homeostasis in AD, and play a role in the impaired Aβ peptide metabolism responsible for progression of dementia. Reactive oxygen species (ROS) affect AD by inducing oxidation of lipids, proteins, and nucleic acids and impairing Aβ clearance by the low density lipoprotein receptor-related protein (LRP1) through its oxidation.

The hazard ratio of AAA for dementia in this study was 1.422, and the reason for this was deduced based on the mechanisms of AAA occurrence. However, since this deduction is only a possibility, further research is needed. In addition, we examined whether there was a difference in dementia incidence according to the treatment method of AAA, that is, the difference between the surgical group and non-surgical group or the OSAR group and EVAR group, but there were no significant differences.

In this study, all of these factors were related to dementia, but there were differences in the directions of the interactions. Synergy was present with hypertension because it uniquely influenced dementia with AAA.

| AAA                      | N    | Event | Duration | Rate     | Model 1                  | Model 2                  | Model 3                  | Model 4                  |

Table 4. Hazard ratio of AAA for incidence of dementia. OSAR Open surgical aneurysm repair, EVAR Endovascular aneurysm repair, Surgical group divided into OSAR and surgical groups.
However, other factors influenced the occurrence of dementia in various ways, indicating a common denominator with AAA. As a result, the HR of AAA for dementia was decreased statistically.

Based on the results revealed in this study, the relationship between AAA and Dementia should be confirmed with a prospective controlled study in the future, and it should be studied what mechanism such a relationship is caused by. In addition, although it could not be conducted in this study, it seems necessary to study whether there is a difference in the incidence of dementia in ruptured AAA and unruptured AAA patient groups.

The present study has several limitations. First, this study was a retrospective analysis. To overcome this, the influence of each variable was adjusted through a multivariate logistic regression model. However, control of the confounders among variables was not achieved. Second, diagnosis of AAA and dementia and identification of other risk factors solely were based on diagnostic codes, possibly introducing bias. For example, in the case of dementia, there is no way to confirm whether it is an accurate diagnosis made by neurologist. Third, considering the time of onset, a rough causal relationship might be inaccurately inferred because of the it is a retrospective nature of the study. Also, the degree of cognitive impairment and issues such as AAA diameter are not known, so the correlation between these could not be demonstrated clearly. Finally, due to the lack of data, the genetic factor could not be considered.

However, our study also has a number of strengths. First, we believe that this is the first study to not only demonstrate the relationship between AAA and dementia, but also to illustrate the effect of AAA on dementia in relation to each risk factor. Second, this study used a large, national sample with a relatively long follow-up period.

Conclusions

We found that AAA was associated with increase in the risk of dementia regardless of AD or VD, even after adjusting for several comorbidities. These finding suggest that continued follow-up in AAA patients might be needed to permit early detection of signs and symptoms of dementia. In particular, surveillance is needed when high blood pressure accompanies AAA or if AAA occurs in the absence of history of heart disease in a patient younger than 65 years. However, to further confirm our findings, a large-scale prospective study is necessary in the future.
