Nonalcoholic fatty liver disease (NAFLD) is common in the elderly, in whom it follows a more severe course due to worse hepatic and extrahepatic manifestations. The former include nonalcoholic steatohepatitis and hepatocellular carcinoma; the latter include cardiovascular and metabolic complications. The pathophysiology, diagnosis and principles of treatment that are specifically relevant to elderly patients with NAFLD are critically reviewed here. Based on these findings, we conclude that a more accurate understanding of the molecular mechanisms of geriatric NAFLD will help in identifying the most appropriate diagnostic and therapeutic approach in the individual elderly patient.

Core tip: Nonalcoholic fatty liver disease (NAFLD) is a common disease in the elderly, in whom it follows a more severe course due to worse hepatic and extrahepatic manifestations. The former include nonalcoholic steatohepatitis and hepatocellular carcinoma; the latter include cardiovascular and metabolic complications. The pathophysiology, diagnosis and principles of treatment that are specifically relevant to elderly patients with NAFLD are critically reviewed here. Based on these findings, we conclude that a more accurate understanding of the molecular mechanisms of geriatric NAFLD will help in identifying the most appropriate diagnostic and therapeutic approach in the individual elderly patient.
Bertolotti M, Lonardo A, Mussi C, Baldelli E, Pellegrini E, Ballestri S, Romagnoli D, Loria P. Nonalcoholic fatty liver disease and aging: Epidemiology to management. *World J Gastroenterol* 2014; 20(39): 14185-14204 Available from: URL: http://www.wjgnet.com/1007-9327/full/v20/i39/14185.htm DOI: http://dx.doi.org/10.3748/wjg.v20.i39.14185

**BACKGROUND**

Increased life expectancy has resulted in a dramatic surge of the median age of the population. Given that such a trend is expected to continue, the increased proportion of elderly and very elderly people in future decades will undoubtedly represent a relevant challenge in terms of health costs and proper resource allocation[1]. With aging, the liver undergoes substantial changes in structure and function that are associated with significant impairment of many hepatic metabolic and detoxification activities[2-10] (Table 1).

Non-alcoholic fatty liver disease (NAFLD), the spectrum of hepatic disorders embracing uncomplicated fatty liver (i.e., “pure steatosis”) and nonalcoholic steatohepatitis (NASH) is associated with features of metabolic syndrome (MS) and several hepatic and extra-hepatic complications[11,12]. Not uncommon in young adults, in children and teen-agers[13-15], NAFLD occurs more often in males than in females[16] and affects mainly the middle-aged and the elderly given that that risk factors for its development tend to increase in prevalence with advancing age[16,17,18]. Worryingly, older patients show more severe biochemical, hematological and histological changes[3], and the female sex is no longer protective with increasing age[18].

No specific recommendations are provided by the available guidelines regarding the diagnostic conduct to be followed in the elderly[10]. Accordingly, a non-invasive diagnostic approach[16] appears to be more rational in this age group. Finally, physical exercise and dietary restriction can be very effective in carefully selected patients and should be used as part of a multidisciplinary approach to overcome the physical limitations not uncommon in older patients[11].

On these grounds, the present review paper aims to systematically and critically analyze bibliographic data that are specifically relevant to NAFLD in geriatric clinical practice.

**EPIDEMIOLOGY AND NATURAL HISTORY OF NAFLD**

Epidemiological data on NAFLD may be derived from studies conducted either in the general population/large cohorts or in selected geriatric cohorts.

**Epidemiology of NAFLD from general population and large cohort studies: Intersected roles of age and gender**

Data from studies conducted in three continents are summarized in Table 2[17,18,21-46]. By analyzing such data, the role of gender and age may be discussed in some detail.

Our group previously reported a prevalence of male individuals with NAFLD in published studies[16], supporting a role for endocrine determinants in the development of this condition. Most Asian and European studies strongly confirm such a view (Table 2). In males, NAFLD tends to increase from younger to middle-aged groups of individuals and the prevalence of disease begins to decline at the age of 50 or 60. This has been defined as an “inverted U shaped curve”. Of interest, a study by Nakajima, although conducted in a restricted series of liver biopsies, was nevertheless able to demonstrate that advancing age was inversely correlated with steatosis[43].

Consistent with a protective role of estrogens, during their fertile period, women tend to be spared from NAFLD compared to men. However, although they tend to develop the disease approximately 10 years later than men, post-menopausal women are no longer spared from NAFLD. The prevalence of NAFLD in women tends to decrease after the seventh decade of life based on both epidemiological (Table 2) and clinical studies[48]. While hormonal changes have consistently been proposed to account for the varying prevalence rates of NAFLD in either gender, the explanation of decreased rates of NAFLD in the elderly is deemed to reflect either selectively decreased survival in those with NAFLD[17,39] or decreased fatty changes in advanced NASH[49].

**Epidemiology and natural history of NAFLD in the geriatric age group**

Findings from three studies conducted in selected geriatric cohorts are summarized in Table 3[3,52]. Information from such studies needs to be interpreted with caution because the findings may merely reflect bias introduced by restricting the analysis to this relatively unique subset of patients[52]. Accordingly, more extensive, less biased cohort clinical studies need to be conducted before drawing any significant conclusions on the prevalence and risk factors of NAFLD in geriatric patients.

Our understanding of the natural history of NAFLD is based on relatively few studies conducted in the United States and northern Europe (reviewed in[12,33,34]). Based on such studies, it may be concluded that NAFLD carries a risk of both hepatic and extrahepatic disease.

**Table 1 Anatomical and physiological changes associated with aging liver**

| Increased fibrosis with reduced percentage of fat on liver biopsy[3,4]; decreased size mirroring decreased hepatic blood flow[5]; Loss of regenerative capacity, i.e. “replicative senescence” involving cross talks of growth hormone, glycojen synthaze kinase 3β and cyclin D3 and shortening of telomeric ends of chromosomes[5-6]; Increased inflammatory changes, hence the definition of “inflam-aging” which, in its turn, has a detrimental effect on the regenerative response[7]; Defective autophagy[8,9]; Decrease in hepatic free radical scavenging system leads to increased oxidative stress resulting mainly from non-enzymatic processes in the liver[10] and is exacerbated by ethanol drinking[48]. |

| Table 2 Epidemiology of NAFLD from general population/large cohort studies across continents |
| --- |
| Age group | Studies | Prevalence of males | Prevalence of females |
| Young |  |  |  |
| Middle aged |  |  |  |
| Elderly |  |  |  |

**Table 2 Anatomical and physiological changes associated with aging liver**

| Increased fibrosis with reduced percentage of fat on liver biopsy; decreased size mirroring decreased hepatic blood flow; Loss of regenerative capacity, i.e. “replicative senescence” involving cross talks of growth hormone, glycojen synthaze kinase 3β and cyclin D3 and shortening of telomeric ends of chromosomes; Increased inflammatory changes, hence the definition of “inflam-aging” which, in its turn, has a detrimental effect on the regenerative response; Defective autophagy; Decrease in hepatic free radical scavenging system leads to increased oxidative stress resulting mainly from non-enzymatic processes in the liver and is exacerbated by ethanol drinking. |
Table 2  Influences of age and gender on non alcoholic fatty liver disease prevalence: Evidence from population-based and large cohort studies from three continents[17,18,21-46]

| Region | Study | Sample Description | Methods | Results |
|--------|-------|---------------------|----------|---------|
| Asia   | Nomura et al[20], 1988 | Cross sectional study on 2574 Japanese healthy residents (1271 males), age 0-70+ yr, FL in 14% | | Prevalence of FL in persons under 19 yr old was only 1.2%, and increased with age to a maximum (25.6%) in persons 40-49 yr of age and then decreased |
|        | Kojima et al[21], 2003 | Cross-sectional and prospective study on 39151 Japanese first-time examinees, 61% males, 12-yr survey period | | The prevalence of FL was uniformly high in males and declined in those in the 6th and 7th decades. The prevalence in females tended to rise gradually with age and declined in those in their 7th decade of life |
|        | Shen et al[22], 2003 | 4039 administrative officers non-drinkers, aged 20-81 yr, 64% males, FL in 12.9% | | At multivariate analysis the prevalence of FL was positively correlated to several risk factors, including male gender and age > 50 yr |
|        | Fan et al[23], 2005 | This cross-sectional study with randomized multistage stratified cluster sampling included 3175 subjects (1218 men) with a mean age of 52 yr. FL was found in 661 (20.82%) subjects | | Age-adjusted prevalence of FL was significantly higher in men than women, and LRA showed that male gender was closely related to FL. The prevalence of FL increased with age in both sexes, peaking in women 60-69 yr of age, and in men 40-49 yr of age. Interestingly, the prevalence was higher in males than females under the age of 50, but was lower in males than females among people older than 50 yr |
|        | Chen et al[24], 2006 | The cross-sectional community study examined 3245 adults in a rural village of Taiwan. The prevalence of NAFLD was 11.5% (327/3245) | | Male sex was an independent risk factors for NAFLD in the general population. Age > 65 yr was inversely related to NAFLD |
|        | Park et al[25], 2006 | Cross-sectional study was performed with data obtained from 6648 subjects, all of whom were older than 20 yr of age (3530 men and 3118 women). The unadjusted and age-adjusted prevalences of NAFLD were 18.7% (23% in men, 13.7% in women) and 16.1% (21.6% in men, 11.2% in women), respectively | | NAFLD prevalence was higher in men than in women. Age was an independent predictor of NAFLD in women only. Menopause status was an independent predictor of NAFLD |
|        | Zelber-Sagi et al[26], 2006 | A cross-sectional study of a subsample of the Israeli national health survey (n = 352). Three hundred and twenty-six subjects (53.4% male, mean age 50.5 ± 10.3) met the inclusion criteria. The prevalence of primary NAFLD was 30% (25%-35% 95%CI) | | Male gender was found to be an independent risk factor for NAFLD which remained significant even after adjustment for obesity and abdominal obesity |
|        | Zhou et al[27], 2007 | A cross-sectional survey of a random sample of 3543 over 7-yr-old inhabitants in 6 urban and rural areas in China. Among the 3543 subjects, 609 (17.2%) were diagnosed having FLD (18.0% males, 16.7% females, P > 0.05). Among them, the prevalence of confirmed alcoholic liver disease (ALD), suspected ALD and nonalcoholic fatty liver disease (NAFLD) were 0.4%, 1.8%, and 15.0%, respectively. The prevalence rate (23.0%) was significantly higher in urban areas than (12.9%) in rural areas | | The prevalence rate was significantly higher in men than women under the age of 50 yr. However, the opposite phenomenon was found over the age of 50 yr |
|        | Eguchi et al[28], 2012 | A cross-sectional study was conducted among 8352 subjects who received health checkups from 2009 to 2010 in three health centers in Japan | | Multivariate and logistic regression analysis indicated that male gender was among the independent risk factors for FLD |
|        | Al-hamoudi et al[29], 2006 | Prospective study among 1512 patients referred for ultrasonography in Saudi Arabia | | The overall prevalence of NAFLD was 29.7% |
|        | Wang et al[30], 2013 | Chinese case-control study based on all 4226 adults above 60 yr of age from a previously cohort investigated compared to 3145 randomly selected younger controls (< 60 yr) from the same cohort. NAFLD was higher in the elderly (26.7%) than in the non-elderly (22.8%) and similar in the elderly between men and women (26.6% vs 27.0%, P > 0.05) | | The prevalence of FLD is higher in the elderly, and is broadly related to the same metabolic risk factors as in the non-elderly. However, female-sex is no longer protective with increasing age, and the prevalence of steatohepatitis with advanced fibrosis is estimated to be considerably higher in the elderly FLD patients than in the younger FLD controls |
|        | Foster et al[31], 2013 | 3056 participants of the Multi Ethnic Study of Atherosclerosis were included in this study. NAFLD was defined as LS ratio < 1, the prevalence of NAFLD was and 11 % in African Americans | | Younger age was among the independent correlates of NAFLD in this population |
|        | Xu et al[32], 2013 | Cross-sectional study on 6905 nonobese (BMI < 25). Risk factors for the development of NAFLD were assessed in a subsequent prospective study in NAFLD-free individuals at baseline, 494 of whom had developed NAFLD during the 5-yr follow-up. Prevalence of NAFLD was 7.27% | | Older age and male gender are associated with both the prevalence and the incidence of novel NAFLD cases in a non obese Chinese population |
|        | Yan et al[33], 2013 | Random sampling of 3762 adults Chinese residents. Ultrasonography revealed fatty liver in 1486 residents with a prevalence of 39.5% | | At univariate analysis, NAFLD cases were statistically younger and more often males |
| Europe | Lonardo et al[34], 2006 | Hospital cohort study of 449 individuals undergoing both liver and carotid US evaluation for clinical indications | | U-shaped curve with NAFLD peak prevalence in the 30-39- and 40-49 age groups. The phenomenon may either reflect a decrease of risk factor for NAFLD, (e.g., obesity) or selectively increased mortality among those with FL. At logistic regression analysis FL is more common in younger male individuals |
Crypotic cirrhosis and hepatocellular carcinoma

Data suggest that in middle-aged individuals (especially in the 45-54 year-old age group), NAFLD is a strong independent risk factor for cardiovascular (CV) mortality[38]. NASH-cirrhosis is expected to occur in older ladies with multiple metabolic derangements and moderately raised liver enzymes because of the following four reasons: (1) the male sex is typically prone to premature coronary deaths; (2) NAFLD occurs in women later than in men (Table 2); (3) female gender and older age are significantly associated with severe fibrosis[39]; and (4) younger ages are associated with more elevated liver enzymes[33]. Such a prediction is confirmed by Ludwig et al[33] and by more recent evidence. Caldwell et al[40,41], by comparing different series of cirrhosis due to varying etiologies, concluded by inference that “cryptogenic cirrhosis” featuring a prevalence of female gender, associated metabolic conditions and slightly raised liver enzymes is nothing but NASH-cirrhosis.

Bugsnesi et al[39] group went further in identifying the risk of hepatocellular carcinoma (HCC) as a part of the NAFLD disease spectrum, confirming early hypotheses published as early as in 1990[40].

Risk factors for HCC in NAFLD include advanced age, type 2 diabetes (T2D) and cirrhosis[41-43]. Of concern, however, is that HCC may also develop against the background of non-cirrhotic NAFLD[44,45] accounting for the finding that these patients are missed by surveillance programs and are diagnosed later than those associated with viral etiology[46,47]. This is of importance given that, by expanding the percentage of cancers amenable to effective treatments, surveillance for HCC is deemed to improve the survival rates of elderly patients[48].

In the elderly, decreased cytochrome P450 activity can affect drug metabolism, increasing the susceptibility to drug-induced liver injury. Immune responses against pathogens or neoplastic cells are reduced in the elderly, although these individuals may be predisposed to autoimmunity through impairment of dendritic cell maturation and reduction of regulatory T cells. These changes in immune functions could alter the pathogenesis of viral hepatitis and autoimmune liver diseases, as well as the development of HCC[49].

Cardiovascular disease, metabolic complications, extrahepatic cancer

As is now clear from consistent evidence in the literature, NAFLD stands not only as a primary disease of the liver but rather as a systemic condition with an inherent increased risk for CV disease (CVD). Evidence for a link between NAFLD and CVD, notably including atherosclerosis, which occurs independent of components of MS, has extensively been reviewed by our group and others[12,54,70-73]. Such a view is specifically confirmed in elderly people.

By evaluating 810 males and 1273 elderly women in Japan, Akashoshi et al[58] demonstrated that NAFLD was associated with coronary risk factors independent of obesity in either gender.

Evidence for those NAFLD patients who are T2D-free at baseline to develop the disease during the follow-up period have been extensively reviewed elsewhere[12,54].

[1-66,67]
In this prospective study, 91 octogenarians who were admitted to the rehabilitation departments of a geriatric hospital were compared to 46 NAFLD young patients.

In this retrospective, cohort study set in a tertiary liver clinic in United Kingdom. Three hundred and fifty one consecutive biopsy-proven NAFLD patients were divided into an older (≥ 60), a middle-aged (≥ 50 to < 60) and a younger (< 50) group.

A cross-sectional analysis of adult participants who were prospectively enrolled in the NASH Clinical Research Network studies. Participants were included based on availability of the centrally reviewed liver histology data within 1 year of enrollment, resulting in 61 elderly (age ≥ 65 yr) and 735 nonelderly (18-64 yr) participants.

Table 3  Selected cohort studies of geriatric patients[51,50,52,13,14]  

| Study                | Participants | NAFLD | Mild to moderate NASH | Severe NASH | Advanced fibrosis |
|----------------------|--------------|-------|-----------------------|-------------|-------------------|
| Kagansky et al[51], 2004 | 91 octogenarians | NAFLD is a common and benign finding in the elderly population, in whom it is not associated with the metabolic syndrome |
| Frith et al[15], 2009 | In this prospective study, 91 octogenarians who were admitted to the rehabilitation departments of a geriatric hospital were compared to 46 NAFLD young patients | NAFLD affects mainly the middle-aged and the elderly. Older patients show more risk factors and more severe laboratori alterations and histological changes, with cirrhosis having a significantly more advanced age than those with milder disease |
| Noureddin et al[52], 2013 | In this retrospective, cohort study set in a tertiary liver clinic in United Kingdom. Three hundred and fifty one consecutive biopsy-proven NAFLD patients were divided into an older (≥ 60), a middle-aged (≥ 50 to < 60) and a younger (< 50) group | The main outcomes were the presence of NASH and advanced fibrosis. Compared to nonelderly patients with NAFLD, elderly patients had a higher prevalence of NASH (56% vs 72%, P = 0.02), and advanced fibrosis (25% vs 44%, P = 0.002). Compared to nonelderly patients with NAFLD, elderly patients with NASH had higher rates of advanced fibrosis (35% vs 52%, P = 0.03), as well as other features of severe liver disease including the presence of ballooning degeneration, acidophilic bodies, megamitochondria, and Mallory-Denk bodies (P ≤ 0.05 for each). |

Clearly, in the elderly, the combination of T2D with NAFLD is likely to manifest a high-risk interaction[82].

Of particular concern is that NAFLD was associated with osteoporotic fractures in middle-aged and elderly men in a recent Chinese study[77].

Finally, a line of research has highlighted NASH (but not simple steatosis) as an independent risk factor for (particularly right-sided) colonic adenomas and advanced neoplasms[78]. Given the strong age-dependency of the disease, findings from this study suggest that colorectal cancer screening is strongly indicated in elderly individuals with NASH.

In conclusion, NAFLD is neither an uncommon nor benign disease in the aged individual.

Elderly people have a high risk for strongly age-dependent hepatic and extra-hepatic complications.

Awareness of NAFLD epidemiology and natural history allows prompt recognition of the disease and the management of complications.

Figure 1A summarizes the epidemiology of NAFLD with respect to age (adapted from References[84,75]).

### PATHOPHYSIOLOGY OF AGE-ASSOCIATED METABOLIC ALTERATIONS

#### Liver

An age-specific pattern of liver disease cannot be defined[84,85]; nonetheless, a number of pathophysiological changes have been described with aging, which can ultimately affect hepatic lipid metabolism.

The reduced liver function, which occurs with aging, has been causally associated with a decline in hepatic blood flow and liver volume[89]. Specific alterations in the metabolism of drugs with a high hepatic extraction rate have been described[85]. However, the metabolic impact of such changes remains unclear. The possible role of the alterations in drug disposition on the progression of liver disease has been commented above[89].

Age-related alterations in hepatic cholesterol homeostasis are poorly defined. Epidemiological evidence supports increased serum cholesterol values that tend to plateau in very old individuals[83] and an increased prevalence of gallstone disease[83] with aging. Again, the underlying mechanisms are incompletely defined; a limited number of reports on in vivo studies in humans have described a reduction in low density lipoprotein turnover[84,85] and an increase in biliary cholesterol output, possibly related to a decrease in cholesterol degradation to bile acids[83,86]. Data from humans also suggest that a reduction of whole body, and presumably hepatic, cholesterol synthesis occurs with aging[87].

The pathogenesis of NAFLD undoubtedly involves IR[88-91]. However, the role of IR as a determinant of age-related liver disease has been recently questioned on the grounds that it may represent a compensatory rather than a causal mechanism[90]. Age-related decreases in hormones such as insulin-like growth factor-1 and dehydroepiandrosterone contribute to NAFLD development via increased IR[93-97].

The role of glucocorticoids in the balance between liver injury and protection is controversial[98]. Hypercortisolism may associate with NAFLD, even if its prevalence in this condition is lower than expected[99], the anti-inflammatory effects of endogenous corticosteroids have been evoked in this regard.

The molecular mechanisms leading to hepatic steatogenesis may theoretically involve increased fat intake (dietary uptake and lipogenesis) or decreased fat output (beta-oxidation, lipoprotein secretion)[84,100,101]. The reduced beta-oxidation was related to reduced hepatic expression of the nuclear receptors of the peroxysome proliferator-activated receptors family (PPARs), whereas the expression of liver X receptors (LXRs) was enhanced[90,102]. The role of other nuclear receptors of the hepatocyte nuclear factor (HNF) family cannot be ruled out as well[96,102].

Interestingly, an inverse correlation between NAFLD and serum levels of adipocyte-fatty acid binding protein, an intracellular lipid transporter, has been reported in the elderly[104].

Human NAFLD in the elderly is frequently more
severe and therefore carries a worse prognosis than in younger age groups. This finding has also been substantiated in a murine model of steatohepatitis. Aging-related alterations of the pro-inflammatory vs anti-inflammatory balance (described as the “inflamm-aging” theory) may represent the biological background of these findings.

The pivotal role of inflammation in the pathogenesis
of liver steatosis has been emphasized in the literature; the link between insulin resistance and inflammation and the possible role of JNKs in the progression of this condition has been clearly defined, along with the involvement of endoplasmic reticulum stress and of the unfolded protein response.[71]

In addition, hormonal changes involving the GH/IGF axis have been related to inflammation in NAFLD. In this context, the adipokine pattern plays an important role; in particular, circulating levels and tissue expression of adiponectin seem to be inversely correlated with NAFLD and its progression[107]; a condition of lower-grade chronic inflammation, where interleukins, in particular IL-6, play a relevant role, is also present[107]. These findings together underscore the complex relationship between insulin resistance and inflammation. Increased spleen volume has also been correlated with this condition and with the alterations in the hormonal and inflammatory pattern.[108]

Finally, the role of the apoptosis-antiapoptosis balance has to be considered; serum concentrations of Bcl-2, a well-known anti-apoptotic marker, were found to be decreased in subjects with NAFLD and NASH[109-111]. Serum levels of Bel-2 also tended to decrease with increasing age,[111], even if the data in very elderly individuals are missing.

Altered distribution of inflammatory cytokines in the different body compartments may further contribute to worsening NAFLD course in the elderly.[112]

Adipose tissue

Aging is typically associated with profound alterations in the amount and distribution of body fat depots with a shift occurring from subcutaneous to visceral localization. Such a shift, in turn, is frequently associated with chronic conditions linked to increased CVR[113,114] such as IR (see above) and other stigmata of MS[115].

The relationship between IR and epicardial fat content, a marker of coronary risk, has been highlighted[115]; evidence in humans, although limited, seems to suggest that in the elderly, epicardial fat accumulation and liver steatosis may be associated[116]. Animal models have confirmed that the amount of adipocytes in fat depots increases with aging[117].

Together with the well-known deleterious effects of visceral fat accumulation and IR, subcutaneous fat loss, and the age-related reduced capacity of subcutaneous fat cells to store lipids may also lead to metabolic complications via lipotoxic effects[109].

Furthermore, the role of preadipocytes, fat cell progenitors, in fat distribution and function has been highlighted in animals[118] and humans[119]. The decline in preadipocyte proliferation and differentiation described with aging may account for an imbalance between lipogenesis and lipolysis, ultimately leading to an increased exposure to free fatty acids and potential lipotoxicity[120,121]. Among the different compounds, saturated fatty acids appear to be particularly hepatotoxic[114,122]. Such toxic potential translates into stress responses, oxidative stress and increased expression of proinflammatory cytokines[123].

The constellation of the alterations in fat cell biochemistry, proliferative capacity and response to inflammation and immune response accompany the process of fat cell senescence.[118]

Indeed, fine tuning of the cross-talk between adipogenic and anti-adipogenic pathways[120] and together with previously mentioned age-related hormonal derangements (GH and IGF-1) and activation of proinflammatory cytokines cascade may play a specific role in NAFLD development in the elderly.

The expression of nuclear receptors and transcriptional modulars in adipose tissue is fundamental in such regulation; the role of PPARγ and other coactivators such as CCAAT/enhancer-binding protein α and β has been clarified[124-127]. A role for liver X receptors cannot be ruled out as well, considering its role in adipogenesis[128], even if no definite evidence with respect to aging is presently available.

Closely related the above mentioned findings, it is important to recall the possible therapeutic implications of reducing abdominal fat, and not only BMI, in improving survival in the elderly, as recently reported[129].

MICROBIOTA IN THE ELDERLY

The human gut microbiome is a complex “superorganism” that is mostly confined to the colon, which contains at least 10^{11} microorganisms, equal to 1.5 kg of microbes of 5000 species with a predominance of anaerobic bacteria.[130-132]. The collective genome of gut microbiota, termed the metagenome, is composed of almost 5 million genes.[133]. Microbiota is considered an “organ within an organ”, with its own functions: it modulates the expression of genes involved in mucosal barrier development, maturation and maintenance of the GI sensory and motor functions and the mucosal immune system[134,135]. It also has a critical role in supporting normal digestion, affects energy extraction from the diet and produces essential nutrients such as vitamins (e.g., vitamin K, vitamin B12 and folic acid) and amino acids, which humans are unable to produce themselves[136,137]. In addition, the intestinal microbiota participates in the defense against pathogens. Compositional changes have been linked with inflammatory bowel disease, irritable bowel syndrome and metabolic disorders, such as T2D and obesity[138-140].

Microbiota and aging

During adulthood, the composition of the intestinal microbiota at the species level is relatively stable. This relative stability, however, decreases in old age[141,142].

Aging produces modifications in the homeostasis of GI microbiota with changes in the prevalence of different bacteria[143]. There is a general agreement regarding large inter-individual variability in older subjects, with a certain country specificity, possibly related to differences in lifestyle and dietary habits[144].
A decrease in Firmicutes has been reported in the Italian population over 60 years and centenarians, which is in contrast with other European populations. The decrease of both Clostridium cluster XIV and Fusobacteria prausnitzii group members was also correlated with frailty, hospitalization, and antibiotic and non-steroidal anti-inflammatory treatment. An age-related increase in Bacteroidetes was found in elderly subjects from Northern Europe but not in Italian elderly and centenarians\textsuperscript{142,145}.

Recent studies observed higher levels of health-promoting bifidobacteria in the elderly in contrast with the common assumption of their decreased levels with age\textsuperscript{144-147}. Certainly, there is an age-related increase in facultative anaerobes (like streptococci, staphylococci, enterococci, and enterobacteria), and pro-inflammatory pathobionts are present in the healthy gut microbiota at low concentrations\textsuperscript{3,42,48,149}.

A decrease in immunomodulatory species belonging to the Clostridium clusters IV and XIV associated with increased pro-inflammatory pathobionts seems to promote inflammatory disorders, and elderly subjects generally have reduced immune function, particularly a deterioration in cell-mediated responses, that affect gut microbiota composition\textsuperscript{150}.

During aging, the impairment of the gut-associated lymphoid tissue and the reduced efficiency of the innate immune defenses are responsible for uncontrolled microbial growth on the enterocyte surface. Indeed, aging is also accompanied by a chronic, low grade overall inflammatory status responsible for the development of pathobionts that can support inflammation with compromised host longevity\textsuperscript{151}. Finally, decreased cellular immune functions can lead to an increased emphasis on antibody-associated responses in the elderly, the subsequent excess of antibodies reflects an increased autoimmunity to self-antigens, predisposing the person to the development of autoimmune diseases\textsuperscript{152-154}.

In addition to immunosenescence and inflamm-aging, lifestyle and dietary habits are other major factors that are responsible for age-related changes in microbiota. Diet impacts on the selection of microbial species are able to optimize energy extraction from dietary substrates\textsuperscript{148,155,156}.

Age-related changes in taste and smell sensations, tooth loss and chewing difficulties strongly influence diet with a reduced intake of fiber, non-starch carbohydrates and proteins, producing modifications in the composition of the bowel ecosystem through a reduction in microbial fermentation. In contrast, reduced acid secretion in the stomach can lead to bacterial overgrowth and subsequent nutrient and vitamin malabsorption\textsuperscript{157-160}.

An unbalanced diet with inadequate intake of vitamin D and B12, calcium and protein can affect both the composition and activity of intestinal microbiota\textsuperscript{161-164}. The common decreased sensation of thirst adversely affects bowel motility and bodily water balance\textsuperscript{160}.

Lifestyle differences, notably including dietary habits, may further affect the geographic-dependent modulation of age on microbiota\textsuperscript{148}.

The poor quality of the diet associated with diminished physical activity in the elderly is also responsible for reduced intestinal motility, which will result in bacterial overgrowth and enhanced metabolic activity, which are difficult to control in an immunosenescent host\textsuperscript{148,155,166}. Age-related neurodegeneration in the enteric nervous system may further contribute to impaired bowel peristalsis\textsuperscript{166,167}.

Increased incidence of disease will be conducive to increased drug consumption by elderly individuals, and this will eventually alter the composition of intestinal microbiota. Most drugs cause hyposalivation responsible for changes in oral microbiota, candidiasis and dysphagia\textsuperscript{168}. Proton pump inhibitors, by lowering gastric pH, may lead to malabsorption of nutrients and microbial overgrowth with associated risk of Clostridium difficile (C. difficile) diarrhea\textsuperscript{169}. Similarly, broad-spectrum antibiotics may lead to overgrowth of pathogenic bacteria such as C. difficile; however, non-absorbable antibiotics (e.g., rifaximin) play a therapeutic role in restoring intestinal microbiota imbalance in several intestinal disorders. The frequent use of nonsteroidal anti-inflammatory drugs is associated with mucosal gastric and duodenal damage with alteration in the local ecosystem\textsuperscript{170}. Finally, the use of opioids may lead to reduced intestinal motility and subsequent bacterial overgrowth\textsuperscript{171}.

Figure 1B illustrates in a schematic way some aspects of the pathophysiology and pathogenesis of the relationship between aging and NAFLD.

NAFLD AND THE GERIATRIC SYNDROMES: SARCOPENIA, FRAILTY, DEMENTIA

The relationship between NAFLD and the typical clinical syndromes associated with aging is ill-defined. Some of the clinical manifestations associated with NAFLD are schematically summarized in Figure 1C.

Sarcopenia and frailty

Sarcopenia is characterized by reduced muscle mass and strength\textsuperscript{172} and replacement of muscle with adipose and fibrous tissue; sarcopenia represents one of the hallmarks of frailty, according to its commonly adopted definition\textsuperscript{173}.

The documentation of an association between fat accumulation in the two tissues (liver and muscle) is relatively recent: morphological imaging has shown that fat content in the paravertebral muscles is correlated with aging and steatosis based on CT analysis and suggested that a reduction in muscle fat can be associated with an improvement of steatosis\textsuperscript{174}. A very recent paper by Hong et al\textsuperscript{175}, on behalf of the Korean Sarcopenic Obesity Study, has provided substantial evidence of a correlation between fat liver content, expressed as the liver attenuation index at CT, and the skeletal muscle mass index determined by DXA.
Sarcopenia and NAFLD may share a number of pathophysiological mechanisms. First, IR has been consistently associated with both conditions. The relationship between IR (and the inherent presence of the MS) and NAFLD has long been recognized[89,90] and critically reviewed[92], as discussed above. The relationship between IR and sarcopenia has been outlined more recently: mediated by mitochondrial dysfunction, IR seems to be a key mediator of the loss of muscle mass[174]. Closing the circle, intramuscular steatosis, which occurs with aging, is associated with IR[177].

A strong relationship links body mass and insulin sensitivity in younger subjects[179] and presumably in the elderly as well.

Interestingly, Hong et al[175] reported an inverse correlation between IR and muscle mass, and a direct correlation between IR and liver fat accumulation, supporting a common pathophysiological substrate of the two conditions mediated by IR itself. Consistent with this view, the MS that is associated with IR has also been associated with NAFLD and sarcopenia[179].

Inflammation represents another factor that potentially links sarcopenia to NAFLD. The association between NASH and inflammation[13], or “inflamm-aging”[106], is well known, as discussed above. A number of epidemiological studies have also shown an association between low grade inflammation and sarcopenia[180]. Several circulating markers of inflammation, such as TNF-α and interleukins (IL-6 in particular) as well as CRP, have clearly been associated with sarcopenia and hepatic steatosis[107,108]. Inflammation is obviously related to IR, as discussed above, and the possible pathophysiological role of increased cytokine release from adipose tissue in the elderly[109] needs to be emphasized.

Finally, a possible role for vitamin D needs to be emphasized. Several lines of evidence have shown that low vitamin D levels are associated with sarcopenia, on the one hand[181], and with NAFLD on the other[182]. A possible common pathophysiological substrate involving shared molecular pathways[183] is highly plausible. However, no such association was observed in Asian populations[175,184].

Dementia
Cognitive decline is another typical feature of pathological aging, which might be associated with liver disease in general. Apart from the well-known association between end-stage liver failure and encephalopathy, the presence of more subtle mechanisms linking “milder” liver disease and some forms of cognitive decline deserves full consideration. For instance, primary biliary cirrhosis and hepatitis C have been correlated with some forms of neuropsychological impairment even in earlier stages of the disease[185,186]. NAFLD has recently been postulated to be an additional risk factor for dementia[187] and is associated with carotid atherosclerosis[107,188] which, in turn, can heavily impair cognitive function.

Apart from the obvious effects of cerebrovascular disease, hormonal alterations associated with NAFLD and possibly linked to IR may play a role; among these, the reduction of IGF-1 levels, as previously discussed[90]. Interestingly, IR was found to be associated with visual and cognitive performance deficits that are strictly linked with frailty and dementia[109].

A possible link with vitamin B12, folate and homocysteine levels also needs to be considered. An association between low levels of vitamin B12 and NAFLD is described in the literature[104]. A similar relationship between dementia and vitamin B12 deficiency is well known[103]; an increased plasma concentration of homocysteine, often caused by cobalamin and folate deficiency, is also a strong, independent risk factor for the development of dementia and Alzheimer’s disease[105]. Although there are no studies that compare the three conditions, the presence of a common pathway linking dementia with NAFLD (vitamin B12 and folate deficiency, higher levels of homocysteine) seems plausible.

**AUTONOMIC AND CARDIOVASCULAR CHANGES IN NAFLD**

Autonomic changes can be measured to assess heart rate variability (HRV), that defines non-invasively and with a high repeatability cardiac autonomic function[191,194]. Frequent symptoms of cardiac autonomic dysregulation are fatigue, orthostatic hypotension and vasovagal syncope.

A strong association links NAFLD, autonomic changes, and MS. Liu et al[99] showed an association between NAFLD and the natural logarithm of standard deviation of NN (lnSDNN) after adjustment for the main CVR factors. Moreover, these authors showed a relationship between MS and an index of sympathetic activity at the symbolic dynamics analysis of HRV[196], indicating activation of sympathetic tone in NAFLD patients.

Studies have reported a high prevalence of autonomic dysfunction in patients with chronic liver disease[197]. Most NAFLD patients do not present with symptoms directly attributable to their liver disease. It is increasingly recognized, however, that those with NAFLD report a wide ranging spectrum of non-specific symptoms, such as fatigue and daytime sleepiness, which may be the presenting complaint and may dramatically impact quality of life[198]. Fatigue is a significant issue in NAFLD, the severity of which does not mirror the severity of hepatic histological changes and dysfunction but is associated with daytime sleepiness and autonomic dysfunction[198]. Dysfunction of the autonomic nervous system leads to symptoms such as postural dizziness and syncope and is also associated with a number of clinical consequences in hepatic diseases such as cognitive dysfunction, falls and fall-related injuries. Falls are also considered a direct consequence of autonomic nervous system dysfunction[198].

Newton demonstrated that a history of falls is common in NAFLD (43%). The proportion of recurrent fallers was significantly higher in a NAFLD cohort compared to controls, with injuries, emergency medical attention, fracture rates and hospital admission all being significantly
more common in the NAFLD group, independent of the presence of T2D or the severity of liver disease[199].

Fatigue is a significant symptom in NAFLD that impacts quality of life and is unrelated to liver disease severity. Newton et al[200] demonstrated a relationship between fatigue and altered autonomic response, higher orthostatic symptoms, and a higher prevalence of positive response to head-up tilt test.

Recognition of systemic symptoms in NAFLD has important implications for patients because many are potentially modifiable with targeted interventions. Several authors demonstrated that an 8-wk resistance exercise program improves sympathovagal balance, expressed as LF/HF ratio measured at rest, and HR and blood pressure response to submaximal exercise[201].

The spectrum of CVD associated with NAFLD extends beyond the commonly recognized premature atherosclerosis. In particular, arrhythmia and non-rheumatic aortic valve sclerosis (a common finding in geriatric practice) have been recently included among CV complications of NAFLD[197].

The prevalence of atrial fibrillation (AF) increases from approximately 1% in individuals less than 55 years of age to approximately 10%/12% in those older than 80 years of age[202]. Along with older age, many pathologic conditions such as obesity, hypertension, coronary heart disease, heart failure and heart valve disease are the strongest risk factors for new-onset AF, which is a disease associated with high rates of hospitalization and death. Not unexpectedly, given that NAFLD is associated with multiple abnormalities in cardiac structure and function and shares multiple cardiometabolic risk factors with AF, an association between NAFLD and an increased risk of incident AF in patients older than 60 years and T2D, independent of other CVR factors[203] has recently been reported. It may be postulated that NAFLD is a marker of ectopic fat accumulation in other tissues, including both the myocardium and pericardium. Rijzewijk et al[204] and Ng et al[205] showed that the intramyocardial fat content, as detected by proton magnetic resonance spectroscopy, was greater in patients with T2D than in nondiabetic controls and was associated with LV diastolic dysfunction. Moreover, it is possible that NAFLD is not only associated with the risk of AF as the consequence of the shared risk factors but that NAFLD per se might contribute to the development and persistence of AF, through the systemic release of pathogenic mediators from the steatotic and inflamed liver, including C-reactive protein, interleukin-6, tumor necrosis factor-alpha, plasminogen activator inhibitor-1 and other inflammatory cytokines; these pathogenic mediators are remarkably higher in patients with NAFLD than in those without, as commented above, and may play a role in the development and persistence of AF, possibly by inducing structural and/or electrical remodeling of the atria[206,207].

Finally, plasma homocysteine levels, a well-known risk factor for CV and cerebrovascular disease, are higher in patients with NAFLD[208]. No direct evidence for a correlation that links aging, NAFLD, homocysteine levels and CV disease is available; however, an association of these factors, as mentioned above for dementia, seems likely.

**PRINCIPLES OF NAFLD MANAGEMENT IN THE ELDERLY**

**Lifestyle changes**

Given that geriatric NAFLD is not a benign disease, elderly patients have a high necessity of treatment. Of concern, lifestyle changes including diet and exercise, which are universally recommended as a first-line approach[19] and which may particularly improve autonomic dysfunction[204], are unlikely to be accepted by elderly individuals. Therefore, the results appear to be largely unpredictable[208] in this specific age-group, particularly regarding increased physical activity[209].

The findings that decreased choline intake is associated with increased fibrosis in postmenopausal NAFLD women[209] and that fish consumption decreases HCC risk[210,211] fully support the recommendation for a balanced diet in the elderly NAFLD patient[212].

**Drug treatment**

Drug treatment is an alternative/adjunctive approach to lifestyle changes. Such a choice might, in principle, appear to be more effective than lifestyle changes. However, to date, no drug has been specifically approved for use in NAFLD[208]. Moreover, current guidelines provide no specific therapeutic recommendations for those older than 65 years[19]. Finally, aging and NAFLD per se may expose these patients to a higher risk of polypharmacy and adverse drug reactions including drug-induced liver injury[214,215].

In the elderly, special attention should be paid to the early identification of cirrhosis and to the diagnosis and treatment of its complications. No significant differences in diagnostic investigations or treatment options are observed between the elderly and the young except that liver transplantation is more rarely performed in the former age group. Fibrosis progression is best detected and monitored through non-invasive techniques[216]. However, after careful consideration of the cost/benefit balance of this procedure, liver biopsy might be considered in selected elderly patients[217].

Next we discuss the principles of treatment of the main metabolic risk factors associated with NAFLD in the elderly.

**Dyslipidemia**

Dyslipidemia in NAFLD individuals generally requires aggressive management[218]. Statins, the main cholesterol-lowering class of drugs, are the most effective and widely used for the primary and secondary prevention of CVD[219]. Statins are remarkably safe in NAFLD patients[19,220,221]. The available small sample of mostly non-randomized studies have shown limited evidence of hepatic histological benefit in NAFLD[19,222]. Recently,
two studies have shown that statins reduce CV events in patients with increased transaminases presumably due to NAFLD. Moreover, one of them reported that the CVD benefit was greater than in patients with normal liver tests\[224,226\]. Given that CVD is the main cause of death in NAFLD patients\[78\], statins play a key role in NAFLD management\[228\]. Finally, statins may also exert a potentially beneficial role both on portal hypertension and HCC chemoprevention\[226-230\].

Therapeutic options in the elderly must carefully balance the potential CV benefits vs the possible side effects and risk of drug interactions. No universal guidelines may be proposed, and treatment decisions need to be tailored considering the specific features of the individual patient, such as biological age, comorbidities and functional organ impairment\[231,232\].

**Diabetes**

Metformin is the first-line drug for the treatment of T2D. Despite beneficial effects on IR, it exerts only a small effect on serum aminotransferases and fails to improve liver histology in NAFLD\[233\]. Accordingly, metformin should not be used in non-diabetic NAFLD patients\[19\], although it has important beneficial effects on NAFLD complications/comorbidities; metformin moderately reduces the risk of HCC\[233-235\] and significantly decreases arterial stiffness, a predictor of cardiovascular mortality\[236\]. A particular concern in the elderly is represented by the frequent impairment of liver function, requiring the need for individualized dosage and warning that metformin is contra-indicated in the presence of overt kidney failure.

Glitazones (i.e., pioglitazone) are recommended by current guidelines for the treatment of subjects with NASH. Large randomized controlled trials reported a beneficial effect of pioglitazone on systemic IR and liver histology, although the advantage was limited for fibrosis\[19,20,207-210\]. However, the beneficial effects on liver histology disappeared after treatment discontinuation\[212\]. Moreover, pioglitazone - due to increased subcutaneous fat depots - is associated with weight gain; the increased risk of congestive heart failure and bone fractures and a slightly increased risk of bladder cancer limit its clinical appeal\[19\], especially in the elderly.

Finally, preliminary evidence for potentially favorable action has been described in an experimental model with pharmacological agents inducing a small increase in mitochondrial uncoupling, leading to an improvement of T2D and IR associated with decreased hepatic steatosis\[241\].

**Hypertension**

Angiotensin receptor blockers are widely used antihypertensive agents with a well-characterized safety profile. Chronic liver damage up-regulates the local tissue renin-angiotensin system, which contributes to the recruitment of inflammatory cells and the development of fibrosis\[78\]. Some animal and small sample human studies have suggested that angiotensin receptor blockers improve serum liver enzyme levels and histological features of NAFLD; however, further larger clinical trials are needed to corroborate these findings\[78\].

Recently, telmisartan has prevented hepatocarcinogenesis via inhibited hepatic angiogenesis in a rat NASH model\[242\].

When considering treatment with blood pressure-lowering agents, attention needs to be paid to the risk of orthostatic hypotension (see above).

**Obesity**

The association between NAFLD and obesity in the elderly may be less relevant due to a physiologic weight loss occurring with aging\[239\]. Lifestyle modification through hypocaloric diet and increased physical activity is the mainstay of the treatment of obesity. A 5% to 10% weight loss is recommended to improve steatosis and NASH\[19\]. Consolidated habits and common physical limitations hamper lifestyle changes in the elderly. No specific drugs are approved for weight-loss, and indications to perform bariatric surgery are restricted by reduced life expectancy and comorbidities of elderly patients.

**Vitamin E**

Vitamin E (800 IU/d) has been shown able to improve NASH histological features (except for fibrosis)\[19\]. However, no long-term follow-up data are available, and this vitamin is not recommended in those with diabetes\[243\]. Of major concern, high-dose Vitamin E supplementation has been linked to increased all-cause mortality\[244\].

**Vitamin D**

Vitamin D deficiency is common in the elderly\[245\]. An increasing body of evidence suggests that low vitamin D status is associated with NAFLD and its histological severity as well as to T2D, MS and CV events\[78\]. Randomized clinical trials are needed to determine whether vitamin D supplementation improves NAFLD and reduces the incidence of cardiovascular outcomes.

**Prebiotics and probiotics**

Dietary prebiotic consumption, which modulates gut microbiota\[246,247\], although associated with subjective satiety, reduced postprandial glucose and insulin concentrations, exhibits inconsistent results regarding total energy intake, body weight, gut peptides, insulin sensitivity, serum lipids, inflammatory markers and immune function\[247\]. Moreover, despite encouraging results in animals\[248-250\], the effect of probiotics on metabolic parameters have provided conflicting results in humans. Transplantation of intestinal microbiota from lean donors improves insulin sensitivity in subjects with MS\[251\]. The wide use of this interesting approach, however, is likely to be limited by the potential risk of transmitting the recipient (unknown) pathogens. Further studies are needed to identify strategies to target gut microbiota composition as an innovative NAFLD treatment in the elderly.
CONCLUSION

Aging is a major social and economic challenge that will steadily increase in the coming decades. NAFLD is expected to play an important role in age-related liver disease in the setting of the secular worldwide trend towards an increment of metabolic diseases, notably including those associated with reduced insulin sensitivity such as obesity and T2D.

Of concern, NAFLD in the elderly is expected to carry a substantial burden of NASH, cirrhosis and HCC, which along with the worrying extra-hepatic manifestations and correlates of disease, makes proper identification and management of this condition a major task for clinical geriatricians and geriatric hepatologists. Careful consideration of the aspects that are peculiar to elderly subjects, including the typical geriatric syndromes (frailty, multimorbidity, polypharmacy, and dementia), is also required.

Proper treatment strategies will have to consider the peculiarities of the geriatric population and will require a multidisciplinary approach. Non-pharmacological treatment (diet and physical exercise) has to be individually tailored considering the physical limitations of most elderly people and the need for an adequate caloric supply. Similarly, the choice for drug treatment must carefully balance the benefits and costs in terms of adverse events and pharmacological interactions, in the common context of both multiple comorbidities and polypharmacy.

Further epidemiological and pathophysiological insight is warranted. More accurate understanding of the molecular mechanisms of geriatric NAFLD will help in identifying the most appropriate diagnostic and therapeutic approach in individual elderly patients.

ACKNOWLEDGMENTS

This review article is dedicated to the memory of late Professor Paola Loria, M.D.
