Sexual practices have a significant impact on the vaginal microbiota of women who have sex with women

Erica L. Plummer1,2,10*, Lenka A. Vodstrcil1,2,10, Christopher K. Fairley1,2, Sepehr N. Tabrizi3,4,5, Suzanne M. Garland3,4,5, Matthew G. Law6, Jane S. Hocking7, Katherine A. Fethers2, Dieter M. Bulach8,9, Gerald L. Murray3,4,5,11 & Catriona S. Bradshaw1,2,7,11

Women-who-have-sex-with-women (WSW) are at increased risk of bacterial vaginosis (BV). We investigated the impact of practices and past BV on the vaginal microbiota within a two-year longitudinal cohort of Australian WSW. Self-collected vaginal swabs were used to characterise the vaginal microbiota using 16S-rRNA gene sequencing. Hierarchical clustering defined community state types (cSts). Bacterial diversity was calculated using the Shannon diversity index and instability of the vaginal microbiota was assessed by change of cSt and Bray-Curtis dissimilarity. Sex with a new partner increased the bacterial diversity (adjusted-coefficient = 0.41, 95%CI: 0.21,0.60, p < 0.001) and instability of the vaginal microbiota, in terms of both change of cSt (adjusted-odds-ratio = 2.65, 95%CI: 1.34,5.22, p = 0.005) and increased Bray-Curtis dissimilarity (adjusted-coefficient = 0.21, 95%CI: 0.11,0.31, p < 0.001). Women reporting sex with a new partner were more likely than women reporting no new partner to have a vaginal microbiota characterised by *Gardnerella vaginalis* (adjusted-relative-risk-ratio[aRRR] = 3.45, 95%CI: 1.42,8.41, p = 0.006) or anaerobic BV-associated bacteria (aRRR = 3.62, 95%CI: 1.43,9.14, p = 0.007) relative to a *Lactobacillus crispatus* dominated microbiota. Sex with a new partner altered the vaginal microbiota of WSW by increasing the diversity and abundance of BV-associated bacteria. These findings highlight the influence of practices on the development of a non-optimal vaginal microbiota and provide microbiological support for the sexual exchange of bacteria between women.

The vaginal microbiota has an important role in protecting against a range of adverse obstetric and gynaecological outcomes including miscarriage, preterm birth, and transmission and acquisition of sexually transmitted diseases (STIs) and HIV1–4. The optimal vaginal microbiota of reproductive aged women is typically characterised by low bacterial diversity and high relative abundance of *Lactobacillus* spp., commonly *Lactobacillus crispatus*5–7.

Bacterial vaginosis (BV) is the most common vaginal dysbiosis and is characterised by a decrease in lactobacilli and increase in the diversity and abundance of facultative and strict anaerobic bacteria including *Gardnerella vaginalis*5,8,9. The pathogenesis of BV is complex and mounting epidemiological and microbiological evidence suggests that sexual activity has a role in both BV incidence and recurrence. Inconsistent condom use and new or increased numbers of sexual partners have been shown by meta-analysis to increase BV risk10. Other sexual practices associated with increased risk of BV include penile-vaginal sex11,12, vaginal sex after anal sex12, receptive oral sex with a female partner13,14, and shared use of sex toys between women13,15,16. BV prevalence is high

amongst women who have sex with women (WSW) with estimates ranging from 25–52%\(^{16–21}\). Whether increased prevalence of BV in WSW is due to sexual practices or other factors is not known.

A number of studies have found sexual activity is associated with disturbance of the vaginal microbiota\(^{22–25}\), however there are limited data describing how specific sexual practices influence the vaginal microbiota in WSW. Mitchell et al.\(^{26}\) used culture methods and found that sharing of sex toys with female partners was associated with reduced concentration of \textit{Lactobacillus}, and digital vaginal sex and sex toy use was associated with increased colonization of \textit{G. vaginalis}.

Understanding how specific sexual practices influence the composition of the vaginal microbiota and contribute to vaginal dysbiosis and BV is important in order to develop effective treatment and prevention strategies. The primary objective of our study was to describe the impact of sexual practices on the vaginal microbiota of a subset of women participating in a cohort of Australian WSW.

### Results

**Description of participants at baseline and longitudinally.** Baseline characteristics and sexual practices of participants are summarised in Table 1. Specimens from 102 women were initially selected for inclusion in the study; however two were removed post quality control of sequencing data (as described below), leaving 100 women in the study population. The median age of participants at enrolment was 28 years (interquartile range [IQR] 24–37 years). Most women were Australian born (86%), had tertiary level education (81%) and had a female sexual partner (FSP) at enrolment (72%). Twenty-two percent of women reported a past history of BV.

Table 1. Characteristics of study participants at baseline. Abbreviations: BV, bacterial vaginosis; FSP, female sexual partner; \(^{a}\)Continuous variables dichotomised at median value. \(^{b}\)n = 81 women reported Australian or English ethnicity, n = 8 reported a European ethnicity, n = 8 reported a non-European ethnicity (other ethnicities reported were Chinese, Malaysian/Indian, Indian, Israeli, Chilean). \(^{c}\)Data missing from one participant. \(^{d}\)n = 6 women reported a current MSP (male sexual partner) at baseline. \(^{e}\)n = 47 women reported ≥ 1 MSP in previous 12 months. \(^{f}\)The top five most prevalent taxa in CST5: \textit{Dialister} spp., \textit{Prevotella} spp., \textit{G. vaginalis}, \textit{L. iners} and \textit{Peptoniphilus} spp.
Hierarchical clustering identified eight community state types (CSTs), Fig. 1. Five CSTs were characterised by Lactobacillus; CST1-L. crispatus (n = 152 specimens), CST2-Lactobacillus mixed (comprised of L. crispatus and L. iners; n = 29), and CST3-L. iners (n = 93), CST6-L. gasseri (n = 5), CST8-L. jensenii/L. fornicalis (n = 10). The remaining three CSTs were: CST4-G. vaginalis and diverse (n = 40 specimens), CST5-anaerobic and diverse (n = 28), CST7-Bifidobacterium longum (n = 3). The five most prevalent taxa identified in specimens in CST5 were BV-associated bacteria Dialister spp., Prevotella spp., G. vaginalis, L. iners and Peptoniphilus spp. For analysis purposes, the two small Lactobacillus CSTs (CST6 and CST8) were combined with CST2-Lactobacillus mixed, and CST7-B. longum was combined with other anaerobic dominated specimens in CST5-anaerobic and diverse.

All women at baseline had normal (Nugent Score [NS] = 0–3, n = 92/100) or intermediate microbiota (NS = 4–6, n = 8/100) by the NS method. Most women (n = 90) clustered into a Lactobacillus dominated CST (CST1-L. crispatus (n = 41), CST2-Lactobacillus mixed (n = 19) and CST3-L. iners (n = 30)).

Of the longitudinal specimens with normal (NS = 0–3, n = 204) and intermediate (NS = 4–6, n = 9) microbiota, most (89%) clustered to a Lactobacillus CST (CST1-L. crispatus (n = 111/213, 52%), CST2-Lactobacillus mixed (n = 24/213; 11%) and CST3-L. iners (n = 55/213; 26%)). The majority of incident BV specimens (NS = 7–10, n = 47) clustered with CST4-G. vaginalis and diverse (n = 26/47; 55%) and CST5-anaerobic and diverse (n = 12/47; 26%).

Factors associated with vaginal microbiota diversity. In univariate analyses, sex with a new partner compared with no sex or sex in an ongoing relationship (defined as relationship for >3 months) was significantly associated with increased bacterial diversity of the vaginal microbiota (coefficient = 0.49, 95%CI: 0.30,0.68, p < 0.001; Table 2). Other characteristics associated with increased microbiota diversity included self-reported past history of BV, smoking, having two or more sexual partners in a study interval (i.e. the period of time
Table 2. Characteristics and sexual practices associated with bacterial diversity of the vaginal microbiota. Abbreviations: BV, bacterial vaginosis; SP, sexual partner (may refer to FSP or MSP); NP, new partner (may refer to FSP or MSP); FSP, female sexual partner; MSP, male sexual partner. Missing data for variables included in this analysis occurred in <0.5% of intervals. 1Univariate GEE linear regression, where participant ID is panel variable. The regression coefficient represents the mean difference of Shannon diversity between the reference and comparison group/s for each characteristic/practice investigated. 2Multivariable GEE linear regression, where participant ID is panel variable. 3Longitudinal characteristics were measured as any exposure over the prior study interval (~90 days). No significant associations were identified between Shannon diversity and either hormonal contraceptive use or recent menses. 4There was no dose-response relationship between smoking and Shannon diversity. 5Missing data from a maximum of two intervals for some variables. 6For women reporting different numbers of sexual partners in two or more intervals, the category representing the highest number of sexual partners has been used to calculate n women reporting exposure. 7For women reporting different frequencies of sexual activity in two or more intervals, the most frequent category has been used to calculate n women reporting exposure. 8Sex with a new partner with who first sexual contact was within 90 days. 9No significant associations were identified between Shannon diversity and the following sexual practices with an FSP: Any digital vaginal sex from an FSP, any receptive oral anal sex from an FSP and current FSP with BV symptoms. These practices have been left out to simplify the table. 10Or did not have a FSP. 11No significant associations were identified between Shannon diversity and the following sexual practices with an MSP: Condoms used for vaginal sex, vaginal sex after anal sex, any receptive oral vaginal sex from an MSP, any digital vaginal sex from an MSP, any anal sex from an MSP. These practices have been left out to simplify the table. 12Or did not have a MSP.

Table 3. Characteristics and sexual practices associated with instability of the vaginal microbiota as measured by change of CST between consecutive specimens. Abbreviations: BV, bacterial vaginosis; SP, sexual partner (may refer to female or male partner); NP, new partner (may refer to FSP or MSP); FSP, female sexual partner; MSP, male sexual partner. Missing data for variables included in this analysis occurred in <0.5% of intervals. *Univariate GEE logistic regression clustered for multiple specimens from each participant. †Multivariable GEE logistic regression clustered for multiple specimens from each participant. 1Longitudinal characteristics were measured as any exposure over the prior study interval (~90 days). No significant associations were identified between change of CST and either hormonal contraceptive use or recent menses. *Douching omitted from table due to collinearity – all intervals of douching (n = 5) were accompanied by a change of CST. ‡Sex with a new partner with who first sexual contact was within 90 days. §The following sexual practices/characteristics with an FSP were left out of the table for simplicity: digital vaginal sex, receptive oral anal sex, digital anal sex, and current partner with BV symptoms. No significant associations between change of CST and these sexual practices were identified. ‖Or did not have a FSP. ‡The following sexual practices/characteristics with an MSP were left out of the table for simplicity: condoms use for vaginal sex, anal sex, vaginal sex after anal sex, oral
vaginal sex and digital vaginal sex. No significant associations between change of CST and these sexual practices were identified. Or did not have a MSP. Index specimen refers to the first specimen of each consecutive pair. Majority of CST4 specimens are endpoint specimens which do not have accompanying change of CST information.

between two specimen collections), frequent sexual activity (several times/week), receptive oral sex from any FSP and self-report of BV symptoms (abnormal vaginal odour and/or vaginal discharge; Table 2). Douching and sharing of sex toys had a borderline association with increased diversity.

We included sex with a new partner, frequency of sex, smoking, oral sex and past history of BV in a multivariable model (Table 2). Digital anal sex was not included in adjusted analyses to limit over-fitting the model. Sex with a new partner (adjusted coefficient = 0.41, 95%CI: 0.21,0.60, p < 0.001), frequent sex (adj. coefficient = 0.20, 95%CI: 0.00,0.41, p = 0.049) and past history of BV (adj. coefficient = 0.26, 95%CI: 0.04,0.48, p = 0.018) were significantly associated with increased diversity of the vaginal microbiota. Smoking and receptive oral sex with an FSP were not associated with diversity adjusted analyses.

To explore the relationship between oral sex, exposure to a new sexual partner, and microbiota diversity, we investigated 1) the impact of new partner exposure on diversity stratified by receptive oral sex, and 2) investigated the interaction between new partner exposure and receptive oral sex. Although new partner exposure was significantly associated with microbiota diversity in women reporting oral sex and not in women who did not practice oral sex (Supplementary Table 1), the 95% confidence intervals overlapped, suggesting no statistical difference in the effect of new partner by oral sex, and furthermore there was no evidence of interaction when formally tested (p = 0.110).

Factors associated with instability of the vaginal microbiota. Compositional change (instability) was measured by change of CST and Bray-Curtis dissimilarity score, calculated between consecutive longitudinal specimens.

Eighty-three women (83%) experienced at least one change of CST during the study period, accounting for 138 instances of CST change. Interestingly, changing between different Lactobacillus CSTs (n = 66/138, 48% of all CST changes) was as common as changing from a Lactobacillus CST to CST4-G. vaginalis and diverse or CST5-anaerobic and diverse (n = 50/138, 36%).

Practices significantly associated with change of CST by univariate analysis (smoking and sex with a new partner) were included in a multivariable model with CST of index specimen (i.e. the first specimen of each consecutive pair; Table 3). In the adjusted analysis, sex with a new partner (adjusted odds ratio [AOR] 2.65, 95%CI: 1.34,5.22, p = 0.005) and smoking (AOR 1.79, 95%CI: 1.03,3.11, p = 0.039) were both associated with an increased odds of change of CST when adjusted for CST of index specimen. Additionally, women with a vaginal microbiota classified as CST2-Lactobacillus mixed (AOR = 6.65, 95%CI: 2.81,15.76, p < 0.001), CST3-L. iners (AOR = 3.13, 95%CI: 1.67,5.87, p < 0.001) or CST5-anaerobic and diverse (AOR 13.18, 95%CI: 2.83,61.31, p < 0.001) were more likely to change CST in the next interval compared with women with a vaginal microbiota of CST1-L. crispatus. Having a CST4-G. vaginalis and diverse microbiota was not significantly associated with change of CST, likely because the majority of CST4 samples represented an endpoint specimen i.e. incident BV (n = 26/40, 65%).

By multinomial regression, women reporting sex with a new partner were more likely than women without a new partner to change from a Lactobacillus CST (i.e. CST1/2/3) to a non-Lactobacillus dominated CST relative to not changing CST (relative risk ratio [RRR] = 4.18, 95%CI: 2.06,8.50, p < 0.001). Smokers were more likely than non-smokers to change between Lactobacillus CSTs (RRR = 2.21, 95%CI: 1.15,4.23, p = 0.017) or change from a Lactobacillus CST to a non-Lactobacillus dominated CST (i.e. CST4/5; RRR = 2.04, 95%CI: 1.11,3.75, p = 0.021) relative to not changing CST. Figure 2 summarises changes of CST in each participant longitudinally and indicates when sex with a new partner was reported.

Practices significantly associated with instability of the vaginal microbiota (i.e. increased Bray-Curtis scores between consecutive samples) by univariate analysis were included in a multivariable model that also included CST of the index specimen (Table 4). Sex with a new partner (adj. coefficient = 0.21, 95%CI: 0.11,0.31, p < 0.001) and smoking (adj. coefficient = 0.09, 95%CI: 0.01, 0.18, p = 0.036) were associated with increased instability of the microbiota, adjusted for index specimen. Additionally, having a vaginal microbiota in the index specimen of CST3-L. iners (adj. coefficient = 0.25, 95%CI: 0.15,0.34, p < 0.001), CST4-G. vaginalis and diverse (adj. coefficient = 0.24, 95%CI: 0.05,0.43, p = 0.013) or CST5-anaerobic and diverse (adj. coefficient = 0.44, 95%CI: 0.30,0.60, p < 0.001) was associated with increased instability of the vaginal microbiota longitudinally compared to a L. crispatus (CST1) vaginal microbiota.

Practices impacting the vaginal microbiota composition. After considering factors that influence stability of the microbiota, we looked at specific characteristics and sexual practices that influenced the vaginal microbiota composition by multinomial logistic regression. In univariate analyses (Supplementary Table 2), we found women who reported sex with a new partner in the previous 90 days were more likely than women reporting no sex or sex in an ongoing relationship to have a vaginal microbiota of CST4-G. vaginalis abundant and diverse (RRR = 4.09, 95%CI: 1.69,9.92, p = 0.002) or CST5-anaerobic and diverse (RRR = 5.37, 95%CI: 2.18,13.20, p < 0.001) than one of CST1. Women who reported smoking were more likely than non-smokers to have anaerobic microbiota (CST5) relative to CST1 (RRR = 3.01,95%CI: 1.31,6.92, p = 0.009). Women who reported receptive oral vaginal sex from an FSP or sharing of unwashed sex toys with an FSP were more likely to have a CST4 microbiota, and women who douched or had a past history of BV were more likely to have a CST5 microbiota (Supplementary Table 2). Women reporting recent menses (defined as onset of menses within 7 days
of specimen collection) were more likely than women not reporting recent menses (>7 days from specimen collection) to have a CST2-Lactobacillus-mixed or CST3-L. iners microbiota composition relative to CST1 microbiota, but were not more likely to have a G. vaginalis (CST4) or anaerobic microbiota (CST5).

We included past history of BV, receptive oral sex from a FSP, sex with a new partner, sharing of unwashed sex toys with an FSP smoking and recent menses in a multivariable multinomial regression model (Table 5). Women reporting sex with a new partner were more likely than women reporting no sex or sex in an ongoing relationship to have a CST4-G. vaginalis and diverse (adjusted-RRR = 3.45, 95%CI: 1.42,8.41, p = 0.006) or CST5-anaerobic and diverse vaginal microbiota (adjusted-RRR = 3.62, 95%CI: 1.43,9.14, p = 0.007) relative to a CST1 vaginal microbiota. Women reporting that they shared unwashed sex toys with an FSP were more likely than women not reporting this practice to have a CST4 vaginal microbiota (adjusted-RRR = 2.49, 95%CI: 1.05,5.91, p = 0.038). Women reporting smoking were more likely than non-smokers to have a CST5-anaerobic and diverse vaginal microbiota relative to a CST1 vaginal microbiota (adjusted-RRR = 2.94, 95%CI: 1.16,7.43, p = 0.023). Women with a past-history of BV were more likely to have a CST5 vaginal microbiota (adjusted-RRR = 3.18, 95%CI: 1.13,8.91, p = 0.028), and women reporting recent menses were more likely to have a CST2 (adjusted-RRR = 3.89, 95%CI: 1.58,9.50, p = 0.003) or CST3 (adjusted-RRR = 2.37, 95%CI: 1.14,4.90, p = 0.020) vaginal microbiota.

Discussion
In this longitudinal cohort study of women who have sex with women, specific sexual practices influenced the bacterial diversity, stability and composition of the vaginal microbiota. Sex with a new partner (primarily representing new FSPs) was associated with an increase in bacterial diversity and an increase in compositional change (or instability) of the vaginal microbiota, both in terms of change of CST and increased Bray-Curtis dissimilarity. Furthermore, women who reported sex with a new partner were more likely than women reporting no sex/sex in an ongoing relationship to have a vaginal microbiota characterised by BV-associated anaerobic bacteria or G. vaginalis, relative to an optimal microbiota characterised by L. crispatus. This study highlights the influence of practices on the development of a non-optimal vaginal microbiota and provides microbiological support for the sexual exchange of bacteria between women. These microbiological findings complement the previously reported epidemiological data from the original cohort13,18, which showed sex with a new partner was associated with a 2.5-fold increased risk of BV acquisition.

There is increasing evidence to support the sexual transmission of vaginal bacteria between WSW. Longitudinal studies in this population have shown that one of the greatest risk factors for BV is having a sexual partner with a history of BV, BV symptoms or microbiologically confirmed BV13,14. A recent study demonstrated that incident BV occurred at a median of 4 days post sexual activity in 93% of WSW, indicating a similar incubation period to that of other STIs27. An early study looking at the transmission dynamics of BV demonstrated that transfer of vaginal secretions between women resulted in BV in 11 of 15 women26. Furthermore, high concordance of Nugent Score categories between FSP13,15,17-19 and evidence that women in monogamous relationships share Lactobacillus strains28 in their vaginas supports exchange of bacteria between women during sex. In our study, women who shared unwashed sex toys and/or received oral sex from an FSP were more likely than women not reporting these practices to have an anaerobic or G. vaginalis abundant vaginal microbiota than a microbiota dominated by L. crispatus. Sexual practices are frequently highly correlated, so it is difficult to determine whether one activity has a greater impact on the vaginal microbiota than others. However, both oral sex with an FSP and sex toy use involve exchange of bodily fluids to varying degrees and therefore promote exchange of bacteria between women. Additionally, both practices have been reported as a risk factor for BV10,13,14,16. Collectively, these data suggest that female partner treatment of women with BV may be an effective strategy to improve BV cure and warrants further investigation.

Table 4. Characteristics and sexual practices associated with instability of the vaginal microbiota as measured by Bray-Curtis dissimilarity between consecutive specimens. Abbreviations: BV, bacterial vaginosis; SP, sexual partner (may refer to FSP or MSP); NP, new partner (may refer to FSP or MSP); FSP, female sexual partner; MSP, male sexual partner. Missing data for variables included in this analysis occurred in <0.5% of intervals.

*aUnivariate GEE linear regression clustered for multiple specimens from each participant. The regression coefficient represents the mean difference of Bray-Curtis Dissimilarity between the reference and comparison group/s for each characteristic/practice investigated. bMultivariable GEE linear regression clustered for multiple specimens from each participant. cLongitudinal characteristics were measured as any exposure over the prior follow-up interval (~90 days). No significant associations were identified between beta diversity and either hormonal contraceptive use or recent menses. dSex with a new partner with who first sexual contact was within 90 days. Partner gender was defined by the participant. eThe following sexual practices/characteristics with an FSP were left out of the table for simplicity: digital vaginal sex, receptive oral anal sex, digital anal sex
and current partner with BV symptoms. No significant associations between beta diversity and these sexual practices were identified. 1Or did not have a MSP. 1The following sexual practices/characteristics with an MSP were left out of the table for simplicity: condoms use for vaginal sex, anal sex, vaginal sex after anal sex, oral vaginal sex and digital vaginal sex. No significant associations between beta diversity and these sexual practices were identified. 1Or did not have a MSP. 1Index specimen refers to the first specimen of each consecutive pair. Majority of CST4 specimens are endpoint specimens which do not have accompanying beta diversity information.

Change of CST was common in our study, in accordance with previous reports that show the vaginal microbiota can be highly dynamic. Composition change (or instability) of the vaginal microbiota between consecutive specimens was primarily influenced by the bacteria present in the index specimen. Collectively, women with a low diversity L. crispatus dominated vaginal microbiota were more likely to have a stable microbiota longitudinally and were less likely to experience change of CST than women with a diverse microbiota or a microbiota abundant in L. iners or G. vaginalis. Our findings are consistent with one study that analysed the vaginal microbiota of 32 women sampled twice-weekly for 16-weeks. Gajer et al. reported that L. crispatus and L. gasseri dominated microbiota appeared to be stable, and that sexual activity negatively impacted stability. Interestingly, practices and microbiological characteristics associated with change of CST were highly consistent with those associated with increasing instability of the microbiota (measured by Bray-Curtis), suggesting change of CST may be a useful measure of microbiota instability.

Smoking had a broad ranging effect on the diversity, stability and composition of the vaginal microbiota, and past studies have shown an association between smoking and BV and/or vaginal microbiota composition that was dose dependent. There are a number of possible explanations for this association. Smokers have shown to have reduced oestradiol levels compared non-smokers, and reduced oestrogen has been associated with non-optimal Lactobacillus-deficient vaginal microbiota. Furthermore, it is well established that nicotine has detrimental effects on the immune system, including reduced production of inflammatory cytokines and decreased functionality of neutrophils and macrophages, and nicotine and its derivatives have been detected in the vaginal metabolome. It is possible that modulation of immune responses may result in reduced clearance of G. vaginalis and other BV-associated bacteria (similar to what has been observed for human papillomavirus) or prevent maintenance of an optimal Lactobacillus vaginal microbiota. The association between smoking and vaginal microbiota instability seen in our study is interesting and may be because the microbiota composition that is found more commonly in smokers (i.e. anaerobic and diverse microbiota) is inherently more unstable than others, such as those dominated by L. crispatus. It is also possible that observed associations between smoking and adverse microbiota composition and instability are due to unmeasured confounding; however, the fact that this association has been shown to be dose dependent in some studies and persists in adjusted analysis provides evidence for a biological association.

A number of other factors were associated with vaginal microbiota composition, stability and/or diversity including past history of BV, menses and douching. The finding that past history of BV was associated with both increased bacterial diversity and an anaerobic microbiota may represent persistence or re-emergence of a polymicrobial BV-biofilm, or alternatively the influence of other factors such as host genetics or immune function, diet or contraceptive practices. Both douching and menses have shown in a number of studies to adversely alter vaginal microbiota composition and stability, and consistent with this, we found that douching was associated with anaerobic and diverse vaginal microbiota and had a borderline adverse effect on microbiota stability in univariate analyses. While recent menses did not have an effect on microbiota diversity or stability in our study, it did influence microbiota composition. Women were more likely to have a vaginal microbiota abundant in L. iners (i.e. CST2 or CST3) if their specimen was collected within seven days of onset of menses, consistent with data that shows L. iners grows best on media containing blood.

Hormonal contraception may have a beneficial impact on the vaginal microbiota. However, we found no association between hormonal contraception and microbiota diversity, stability or composition, which may be because only a small number of women reported hormonal contraceptive use in the parent cohort. There are a number of limitations to this study. The study population comprised highly educated women who were predominately Australian born and reported Australian or English ethnicity, which may limit the generalizability of our findings. Specimens were collected every three months which limited our ability to assess immediate effect of sexual practices behaviours on the vaginal microbiota and any short-term fluctuations in microbiota composition. Specimens included in the analysis were not selected randomly or from specified study time points which may have biased results. We did not include negative controls alongside specimens during sequencing, however we removed contaminants previously identified using the same extraction methodology, primer set up and sequencing instrument and the microbiota profiles are consistent with those previously published. Finally, this study did not assess practices or the vaginal microbiota of the sexual partner/s of participants so we cannot definitively prove sexual transmission of BV-associated bacteria is occurring between women. Nevertheless, the microbiota data presented here is consistent with epidemiological data that supports sexual transmission of BV in WSW. This study shows that sex with a new partner is associated with changes in the vaginal microbiota of WSW, including increased diversity and increased abundance of bacteria commonly associated with a non-optimal vaginal microbiota. These findings suggest that sexual exchange of bacteria, including BV-associated bacteria, occurs between female sexual partners, and highlight the influence of specific practices on the development of a non-optimal vaginal microbiota. These data are important for informing strategies to promote a vaginal microbiota that is associated with optimal reproductive health, as well as new approaches to improve BV cure such as female partner treatment.
For the microbiota sub-study, we included all women who developed incident BV (n = 51) and an equal number of women who did not (initially controls were over-selected using a random sort command in Stata/IC (v14.2, StataCorp LP, College Station, USA)). Seven of the 51 women to develop incident BV co-enrolled in the original cohort with their FSP. As such, controls were then frequency matched on co-enrolment status and age to ensure a similar distribution of both variables (for example, the last non co-enrolled control was replaced with the next randomly selected co-enrolled control). Each woman contributed a baseline specimen and an endpoint specimen (BV-specimen from women with incident BV or the 24 month specimen from women without BV). Up to three interim specimens were included for each woman (typically the last two specimens collected prior to the endpoint (BV specimen). If a specimen could not be used/located, an earlier specimen from that participant was used.

Methods

Participant and specimen selection. Participants were selected from the Women On Women's (WOW) Health study, a two-year cohort of 298 WSW designed to examine epidemiological and microbiological factors associated with incident BV.[13,18] Women reported a FSP within 18 months prior to enrolment and were BV negative (NS < 7^th) on three consecutive baseline vaginal smears collected one week apart. Women self-collected a vaginal swab and smear, and completed a detailed questionnaire every three months until study endpoint (diagnosis of incident BV [NS = 7–10] or 24 months without BV). Women were instructed to avoid specimen collection on the heaviest days of their menstrual cycle.[13]

For the microbiota sub-study, we included all women who developed incident BV (n = 51) and an equal number of women who did not (initially controls were over-selected using a random sort command in Stata/IC (v14.2, StataCorp LP, College Station, USA)). Seven of the 51 women to develop incident BV co-enrolled in the original cohort with their FSP.[13] As such, controls were then frequency matched on co-enrolment status and age to ensure a similar distribution of both variables (for example, the last non co-enrolled control was replaced with the next randomly selected co-enrolled control). Each woman contributed a baseline specimen and an endpoint specimen (BV-specimen from women with incident BV or the 24 month specimen from women without BV). Up to three interim specimens were included for each woman (typically the last two specimens collected prior to the endpoint specimen). If a specimen could not be used/located, an earlier specimen from that participant was used.

Ethical approval was obtained from the Human Research Ethics Committees of Alfred Hospital, Melbourne, Australia and the University of Melbourne. All research was performed in accordance with the National Statement

### Table 5. Characteristics and practices associated with vaginal microbiota composition by multivariable multinomial logistic regression

| Outcome by CST | Lactobacillus mixed (CST2) vs CST1 | RRR (95% CI) | P value | Adjusted RRR | P value |
|---------------|----------------------------------|-------------|---------|-------------|---------|
| Self-reported past history of BV | 0.87 (0.35,2.17) | 0.762 | 0.83 (0.33,2.09) | 0.696 |
| Smoker | 1.59 (0.77,3.29) | 0.214 | 1.75 (0.84,3.65) | 0.138 |
| Sex with a NP | 0.62 (0.18,2.19) | 0.460 | 0.57 (0.16,2.00) | 0.384 |
| Receptive oral vaginal sex from FSP | 1.09 (0.56,2.15) | 0.799 | 1.02 (0.51,2.05) | 0.951 |
| Sharing of unwashed sex toys with FSP | 0.92 (0.36,2.32) | 0.859 | 0.75 (0.26,2.18) | 0.600 |

| Outcome by CST | L. iners (CST3) vs CST1 | RRR (95% CI) | P value | Adjusted RRR | P value |
|---------------|-------------------------|-------------|---------|-------------|---------|
| Self-reported past history of BV | 0.69 (0.26,1.87) | 0.467 | 0.66 (0.23,1.93) | 0.450 |
| Smoker | 1.38 (0.71,2.65) | 0.341 | 1.46 (0.72,2.94) | 0.291 |
| Sex with a NP | 1.77 (0.87,3.60) | 0.117 | 1.61 (0.77,3.38) | 0.208 |
| Receptive oral vaginal sex from FSP | 1.09 (0.57,2.12) | 0.799 | 1.01 (0.51,2.01) | 0.977 |
| Sharing of unwashed sex toys with FSP | 0.98 (0.50,1.92) | 0.952 | 1.02 (0.48,2.14) | 0.965 |

| Outcome by CST | G. vaginalis and diverse (CST4) vs CST1 | RRR (95% CI) | P value | Adjusted RRR | P value |
|---------------|---------------------------------------|-------------|---------|-------------|---------|
| Self-reported past history of BV | 1.13 (0.39,3.27) | 0.817 | 1.24 (0.43,3.57) | 0.686 |
| Smoker | 1.72 (0.74,4.01) | 0.207 | 1.69 (0.70,4.08) | 0.240 |
| Sex with a NP | 4.09 (1.69,9.92) | 0.002 | 3.45 (1.42,8.41) | 0.006 |
| Receptive oral vaginal sex from FSP | 2.60 (1.09,6.20) | 0.031 | 1.94 (0.77,4.84) | 0.158 |
| Sharing of unwashed sex toys with FSP | 2.38 (1.04,5.45) | 0.039 | 2.49 (1.05,5.91) | 0.038 |

| Outcome by CST | Anaerobic and diverse (CST5) vs CST1 | RRR (95% CI) | P value | Adjusted RRR | P value |
|---------------|-------------------------------------|-------------|---------|-------------|---------|
| Self-reported past history of BV | 2.82 (1.09,2.27) | 0.032 | 3.18 (1.13,8.91) | 0.028 |
| Smoker | 3.01 (1.31,6.92) | 0.009 | 2.94 (1.16,7.43) | 0.023 |
| Sex with a NP | 5.37 (2.18,13.20) | <0.001 | 3.62 (1.43,9.14) | 0.007 |
| Receptive oral vaginal sex from FSP | 2.17 (0.86,5.46) | 0.099 | 1.67 (0.62,4.94) | 0.308 |
| Sharing of unwashed sex toys with FSP | 1.46 (0.62,3.46) | 0.387 | 2.07 (0.79,5.43) | 0.141 |
| Onset of last menses ≤ 7 days ago | 1.64 (0.55,4.91) | 0.378 | 1.37 (0.41,4.64) | 0.611 |

### Table 5. Characteristics and practices associated with vaginal microbiota composition by multivariable multinomial logistic regression. Abbreviations: CST, community state type; NP, new partner (may refer to FSP or MSP); FSP, female sexual partner. Missing data for variables included in this analysis occurred in < 0.5% of intervals. A multinomial logistic regression with CST1 – L. crispatus as the baseline comparison group. Analysis clustered for multiple specimens from participants (100 clusters). A multinomial logistic regression as described in a adjusted for all other characteristics in the table. Self-reported past history of BV relative to no self-report of past history of BV. A Smoker relative to non-smoker. A Sex with a new partner with who first sexual contact was > 90 days. A Receptive oral vaginal sex from FSP relative to no receptive oral sex from FSP (or no FSP). A Sharing of unwashed sex toys with FSP relative to no toy use/changed condoms on the sex toys/always washed the sex toys between sharing with a partner. A Onset of last menses ≤ 7 days ago relative to onset of last menses > 7 days ago.
on Ethical Conduct in Human Research. Informed written consent was obtained from all participants for the use of their specimens in the current study.

**Laboratory methods.** Swabs were agitated in 1 mL RNAlater (Thermo Fisher Scientific, Waltham, USA) and stored at −80 °C prior to DNA extraction using the MagNA Pure 96 instrument and the DNA and Viral NA small volume kit (Roche Diagnostics, Mannheim, Germany). Dual index primers 341 F/805 R with heterogeneity spacers were used for PCR amplification of the V3-V4 hypervariable regions of the 16s rRNA gene. Libraries were sequenced by Micromon Genomics (Micromon, Monash University, Victoria, Australia) on the MiSeq platform (Illumina, San Diego, CA, USA). Sequence reads are available in the NCBI Sequence Read Archive under Bioproject PRJNA434520.

**Sequence data analysis.** Barcodes were extracted using QiIME v1.9.0 and demultiplexing was performed using idemp (https://github.com/yhwu/idemp). Primers and heterogeneity spacers were removed using TagCleaner standalone version 0.16. Reads were processed using DADA2 v1.6.0. Reads were truncated based on quality profiles (at 250 bases for read 1 and 220 bases for read 2) and were discarded if they had ambiguous bases or exceeded the number of expected errors based on quality scores. Chimera were identified and removed. Taxonomy was assigned using the default RDP Classifier implemented in DADA2 and the Silva reference database (v128). Species level assignment was performed using exact matching in the DADA2 package and taxonomy for *Lactobacillus* spp. was confirmed by a BLAST search against a database of 16s rRNA gene sequences from 158 type strains. Not all ASVs were able to be assigned to species level.

BV-associated bacteria (BVAB) 1 has previously been misclassified as *Shuttleworthia* and BVAB3 is named as *Fastidiosiplia* in the Silva database. We aligned *Shuttleworthia* and *Fastidiosiplia* ASVs against BVAB1 (NCBI GenBank AY724739.1), BVAB2 (AY724740.1) and BVAB3 (AY724741.1) using Clustal Omega (EMBL EBI). *Shuttleworthia* ASV had 100% identity to BVAB1. Two *Fastidiosiplia* ASVs had high identity to BVAB2 (99.50 and 100% identity, respectively), and a third *Fastidiosiplia* ASV had 100% identity to BVAB3. The ASVs were reclassified accordingly.

ASVs were removed if they had a total abundance of less than 0.001% or were present in only one specimen. The ASV table was screened for contaminants previously identified in negative controls, as well as common sequencing contaminants (removed ASVs belonging to *Facklamia* and *Shewanella* genera and Halomonadaceae family). Specimens with fewer than 1000 reads were excluded from analysis. Participants were excluded if they did not have an enrolment specimen or did not have any follow-up specimens.

Diversity metrics and CST were generated using the Vegan package and R Studio [V 1.1.419, Boston, USA] employing R v3.4.3. Alpha diversity was calculated using the Shannon Diversity Index using ASV data. ASVs assigned to the same taxonomy were merged and the relative abundance of each taxon was used for CST identification. Hierarchical clustering of Euclidean distances with Ward linkage was performed on the relative abundance of each taxon and a scree plot of within cluster distances was used to inform the number of CSTs. Bray–Curtis dissimilarity scores were calculated between consecutive paired specimens from each participant. The heatmap was generated using the ComplexHeatmap package and the same metrics used to identify CSTs. Change of CST was defined as change or no change in CST between consecutive paired specimens.

**Statistical analysis.** Statistical models that accounted for repeated measures within individuals were fitted using generalised estimating equations (GEE) to investigate the impact of characteristics and practices on the diversity (Shannon-Diversity Index) and instability (change of CST or Bray–Curtis dissimilarity) of the vaginal microbiota. GEE linear regression analyses were used when the outcome was Shannon-Diversity Index or Bray–Curtis dissimilarity, with the regression coefficient representing the mean difference of each outcome between the reference and comparison group/s for each characteristic/practice investigated. GEE logistic regression was used when change of CST was the outcome. Characteristics and practices deemed significant in univariate analyses (p < 0.05) were included in multivariable analyses.

We also analysed the type of CST change observed. Specimens were allocated one of four change type between sequential specimens: (1) no change; (2) change from one *Lactobacillus* CST to another *Lactobacillus* CST; (3) change from one *Lactobacillus* CST to a non-*Lactobacillus* CST; or (4) change from a non-*Lactobacillus* CST to any other CST. Multinomial regression was used to investigate the relationship between practices and type of CST change relative to the risk of no change, generating relative risk ratios and 95% confidence intervals.

Multinomial regression was also used to assess associations between characteristics and microbiota composition (i.e. CST-classification of a sample). CST1-*L. crispatus* was the reference group for all analyses. This analysis calculated the risk of having a vaginal microbiota of a specific CST (details of CSTs provided in results below) compared to the risk of a vaginal microbiota of CST1, clustering for multiple samples from individual participants.

Characteristics and practices deemed significant in univariate analyses (p < 0.05) were included in multivariable analyses. Statistical analyses were performed using STATA v14.2, unless otherwise specified.

**Data availability** The raw sequencing data are publicly available in the NCBI Sequence Read Archive (SRA) under the Bioproject number PRJNA434520.
